NEW
from Edwards

E606

mass spectrometer

RP361

The Edwards type E606 mass spectrometer is an advanced, 2nd generation instrument with higher sensitivity, faster scanning speeds and broader mass range than any other low cost instrument of the sector field type—or any other type for that matter. It offers the best value-for-money available anywhere in present day mass spectrometry and the E606 is rapidly being established as the standard laboratory tool for flavour research, steroid chemistry, polymer analysis, compound identification etc. It is specially designed for simple, in-line connection to gas chromatographs and can be supplied with a number of alternative sample inlet arrangements, including helium separators.

Low cost:

£8,500 ex-works price for complete instrument including oscilloscope and UV recorder read-out, helium separator etc.

High performance:

Mass range: 18—1350 amu.

Scan speeds: 0.1 sec—900 min for full mass range.

Sensitivity: With in-line GC/MS coupling, less than 1 µg of sample on the column can be detected.

Reliability:

■ Integrated circuitry ■ Ultra "clean" high vacuum system ■ Fully protected ■ Specially designed, high gain electron multiplier with extremely stable, long life Ag Mg dynodes.

Ease of operation:

■ "Open-plan" layout of analyser tube allows easy access to the ion source, magnet carriage, sample inlet etc ■ Fast scanning provides a continuous oscilloscope display of the mass spectrum and simple "fingerprinting" of sample ■ Single button triggering of UV recorder to give immediate record of spectrum ■ Variable electron accelerating voltage allows study of the parent ion or ionisation potentials ■ Data acquisition accessory for digital output to a computer.

we made a successful atomic absorption spectrophotometer —then we made it even better

And that's exactly what Pye Unicam did with the world-famous Unicam SP90 Atomic Absorption Spectrophotometer. It's now the Unicam SP90 Series 2, but it's not just the name that has changed. Absorbance or energy scales can now be presented in linear form on the integral meter or on a pen recorder, with continuous scale expansion of up to 10x for absorbance. Results can also now be shown on a digital display and printout accessory. The sensitivity specification has been increased as a result of improved hollow cathode lamps and excellent optical quality, whilst still preserving the outstanding detection

limits. And, of course, there are all the first-class features and accessories associated with the original SP90 spectrophotometer—like flame emission facilities, a wide choice of flame and burner systems (including nitrous oxide with a new burner head), a three-lamp turret and automatic sampling. For more information and full technical details on this new instrument and the range of hollow cathode lamps, write to Pye Unicam Ltd.

DICTIONARY OF ORGANIC COMPOUNDS

Sixth Supplement, Fourth Edition

Edited by J. B. Thomson

The sixth annual supplement brings the Dictionary of Organic Compounds up to date to the end of 1969, providing, with the dictionary itself and the fifth supplement, the most modern and convenient reference service for organic chemists.

£12 (£12.00) net

Fifth (Cumulative) Supplement

This cumulative supplement, containing 10,000 entries, covers the literature published during 1968 and all the entries in the previous four annual supplements. For this supplement, special prices are available to previous purchasers.

£50 (£50.00) net

Coming shortly:

Formula Index

Lists organic compounds in alphabetical order under their empirical formulae. All entries in the Dictionary of Organic Compounds Main Work and in the 5th Cumulative Supplement are included.

The Birth of Penicillin

and the disarming of microbes

RONALD HARE

A unique description of the discoveries that have enabled us to cure or prevent so many infectious diseases. It is based on the personal experience of the author, a leading bacteriologist, who was present at the discovery of penicillin and has participated in many of the epoch-making discoveries since then.

What do you want in X-ray diffractometry?

People with problems in X-ray diffractometry are very important to the design of Philips X-ray diffraction equipment. After all, if we do not know the problems you are facing, how can we produce the right instruments? But this information alone is not enough. It needs the backing of Philips' own technological experience and vast research effort. The result is a range of equipment that is the most advanced of its type.

Look at what is available for industry and research. Three models of 3kW generators, vertical and horizontal goniometers with diffraction sets, Debye-Scherrer and universal flat plate cameras with all the accessories, high-temperature attachment, automatic sample changer, texture attachment, metallurgical kit, Eulerian cradle, vacuum attachment, auto-focus specimen holder, detectors, tubes, circuit panels – exactly what you want in X-ray diffractometry. And when you suggested a computer-controlled instrument we had the answer in the PW1100 single-crystal diffractometer – complete with all the software you normally have to provide yourself. The fact is, by helping us we are helping you to keep way out in front in X-ray diffractometry. Get the full story from Pye Unicam Ltd – write for free brochures today.

MEDICINE & BIOLOGY

ADVANCES IN ENZYME REGULATION Volume 8

Edited by GEORGE WEBER, *Indiana University School of Medicine*

Contents: Session I—Control Mechanisms in Carbohydrate Metabolism; Session II—Metabolic and Enzyme Control in Avian Systems; Session III—Control Mechanisms in Microorganisms; Session IV—Regulation in Different Organs; Session V—Regulation of Enzyme in Glycogen Metabolism; Session VI—Regulation through Hormone Action; Session VII—Enzyme Induction of Vitro; Session VIII—Regulation and Isozymes; Session IX—Special Symposium Lecture: Sir Hans A. Krebs.

400 pages £7 hard cover

PROGRESS IN BIOPHYSICS AND MOLECULAR BIOLOGY Volume 20

Edited by J. A. V. BUTLER and D. NOBLE

Partial Contents: Three Dimensional Electrical Field Problems in Physiology—R. S. Eisenberg and E. A. Johnson; Organisation of the Cellular Membranes—S. K. Malhotra; The Replication of DNA-containing viruses—A. B. Stone; Nuclear Magnetic Resonance in the Study of Biopolymers and their interaction with Ions and Small Molecules—B. Sheard and E. M. Bradbury; Mechanisms of Enzyme action—S. Doonan, C. A. Vernon and Barbara E. C. Banks.

352 pages £6 10s hard cover

CONTROL OF GROWTH AND METAMORPHOSIS (Animal Hormones Part 2)

P. M. JENKIN

A comparative survey of the sources and actions of those hormones influencing growth, moulting and metamorphosis in Annelida, Gastropoda, Cephalopoda, Crustacea, Insecta, some other Arthropoda and all classes of Vertebrata.

Contents: Chapter I—Introduction; Chapter II—Sources of Hormones related to Morphogenesis; Chapter III—Growth and Mitosis; Chapter IV—Moulting and Metamorphosis; Chapter V—Control of Morphogenetic Hormones.

356 pages £5 hard cover

EVALUATION OF NOVEL PROTEIN PRODUCTS

Edited by A. E. BENDER, R. KIHLEBERG, B. LÖFQVIST and L. MUNCK

Proceedings of the International Biological Programme (IBP) and Wenner-Gren Center Symposium held in Stockholm, September 1968.

Contents: Session 1—The World Food Problem; Session 2—Novel Protein Sources; Session 3—Nutritional Evaluation of Protein Quality I; Session 4—Nutritional Evaluation of Protein Quality II; Session 5—Toxic, Hygienic and Functional Evaluation of Protein Products; Session 6—Effect of Processing and Storage on the Value of Protein Products; Session 7—Proteins in Our Time.

440 pages £7 hard cover

THE CONTROL OF GROWTH AND DIFFERENTIATION IN PLANTS

P. F. WAREING, School of Biological Sciences, University College of Wales, Aberystwyth, and I. D. J. PHILLIPS, Department of Biological Sciences, University of Exeter

Brings together within one book the morphological, physiological and biochemical approaches to all phases of plant development. Recent advances in the knowledge of growth hormones, flowering, dormancy, and senescence are incorporated and the authors have synthesized knowledge obtained in diverse fields of research to gain an understanding of the processes involved in the control of plant development.

Why Pye Chromatography

The crowning success in the design of complex analytical instruments is the achievement of simplicity. You will find it in Pye Analytical Gas Chromatographs. Take the simple, functional glass-to-metal seal, for example. It makes column changing quicker and easier, improves sensitivity by reducing contamination of the gas stream and pushes the effective working temperature of glass columns up to 350°C. Pye gas chromatographs are easy to use because we design them to give you what you want in instrumentation — accuracy, reproducibility, flexibility, simplicity. Two systems are available, both with a wide range of optional modules—
The Pye Series 104 Chromatograph for research or routine work, with many

accessories including wide-range amplifier and auto-solids injection . . . and the Pye Model R Research Chromatograph with modular column oven, unique "total-loss" cooling system and simultaneous two column multi-detector operation.

To learn more about Pye chromatography including industrial instrumentation, the GM60 Gas Chromatograph-Mass Spectrometer system and the DP90 Datacon computerised chromatograph system, write or 'phone today.

Bio-Medical Engineering Exhibition

OLYMPIA
WEST HALL
LONDON
SEPT 15TH - 18TH
1970

The phenomenal growth of the bio-medical engineering industry can be most effectively seen at Olympia this September. The latest instrumentation and equipment from more than 60 companies throughout the world will be displayed and demonstrated. The Bio-Medical Engineering Exhibition presents a unique opportunity to see all the relevant equipment together under one roof.

A lecture programme is being arranged by The Biological Engineering Society who will also be organising a series of scientific displays demonstrating the most recent original research.

10.00 to 18.00 hrs Tues. Weds. Thurs.
 10.00 to 16.00 hrs Fri.

*Sponsored by the publishers of 'Bio-Medical Engineering'.
 Admission tickets and full programme available from the organisers:*

U.T.P. EXHIBITIONS LTD
 36-37 FURNIVAL STREET, LONDON, EC4. Tel: 01-405 4886

Physics and Chemistry in Space

Edited by J. G. Roederer, Denver, and
 J. Zähringer, Heidelberg

Editorial Board

H. Elsässer, Heidelberg
 G. Elwert, Tübingen
 L. G. Jacchia, Cambridge, Mass.
 J. A. Jacobs, Edmonton
 P. Meyer, Chicago, Ill.
 N. F. Ness, Greenbelt, Md.
 W. Nordberg, Greenbelt, Md.
 W. Riedler, Graz
 J. W. Warwick, Boulder, Colo.

The main purpose of Physics and Chemistry in Space is to appraise where we stand, what we know, and what we still need to know in space research. It is mainly addressed to graduate students and researchers who are in the process of getting acquainted with the field. Highest priority is given to a didactically eloquent presentation of the foundation of each subject, with emphasis on recent achievements in understanding. Mature scientists and teachers will also profit from this series of monographs, which should enable them to challenge and clarify their own ideas and to project them into the future.

Volume 1 Geomagnetic Micropulsations

By J. A. Jacobs,
 The University of Alberta
 Edmonton (Canada)
 With 81 figures. VIII,
 179 pages. 1970.
 Cloth DM 36,—
 A detailed account both of the morphology of geomagnetic micropulsations and of the various theories that have been proposed to explain them.

Contents

The Earth's Magnetic Field
 The Morphology of Geomagnetic Micropulsations
 Magneto-Hydrodynamic Waves
 Theories of the Origin of Pc1 Pulsations
 Theories of Pc 2-5 and Pi Oscillations
 Micropulsations and the Diagnostics of the Magnetosphere
 Subject-Index

Springer-Verlag
Berlin
Heidelberg
New York

(Continued overleaf)

Only four controls —but what performance!

Simple to look at... just as simple to use.
The new Unicam SP1000 Infrared
Spectrophotometer.

Give your new lab technician a few minutes' instruction, and you have an immediate capacity for infrared spectra of the highest quality. You might think, because of all that simplicity, that we have sacrificed something along the way. Just one thing—the price. Everything else is comparable to instruments costing very much more.

How is this possible? For one thing we have introduced a high performance Ebert grating monochromator which gives excellent resolution. Then there is an improved pneumatic detector incorporating solid-state circuitry, and a large (20 cm x 48 cm) integral strip chart recorder for supremely clear results. A full range spectrum ($625\text{--}3800\text{ cm}^{-1}$) will take you just two minutes, or for work of the highest precision press the "slow scan" button and wait less than five and a half minutes.

It will certainly pay you to learn more about the SP1000. Or if your needs are even more demanding then there is the Unicam SP1200. Write or 'phone today for a free brochure.

Pye Unicam has a new automatic enzyme analyser. This is what makes it tick.

It is the new Unicam AC61 Programme Delay Unit, which holds the reacting mixture in a spectrophotometer flow cell from 5 seconds to 5 minutes while the change in absorbance is measured.

The whole system – comprised of an automatic chemical processing unit, a spectrophotometer and a recorder – has been designed for versatility and precision at low cost.

The system is simple to operate. Programming takes only a few minutes. Sample and reagent volumes are controlled by preformed templates. No initial sample preparation is required.

Enzyme reaction rates can be measured and

recorded completely automatically at speeds ranging from 12 – 60 an hour, while other chemical analyses can be completed at up to 120 samples an hour.

Above all, the system is backed by methods proved in the Pye Unicam Applications Laboratory and over 20 method sheets are currently available including LDH, CPK, SGOT and SGPT in serum.

Find out more about the Unicam Automatic Analytical System by telephoning or writing to Pye Unicam today.

Precision Instruments

We now have capacity for aluminising certain types of mirrors, at short notice.

SOLE DISTRIBUTORS IN U.K. OF SCHOTT INTERFERENCE FILTERS

Polarimeter Model P.70

A long time has been spent developing this photo-electric polarimeter, and we are now satisfied that it will please the most discerning user. It has the accuracy of rotational measurement that can only be achieved from a ruled circle, plus independent magneto-optical compensation for recording or digital presentation, should it be required.

There are four models from which to choose, all virtually identical in external appearance, but with internal variations to provide the particular facilities that you require.

Why Pye Chromatography

The crowning success in the design of complex analytical instruments is the achievement of simplicity. You will find it in Pye Analytical Gas Chromatographs. Take the simple, functional glass-to-metal seal, for example. It makes column changing quicker and easier, improves sensitivity by reducing contamination of the gas stream and pushes the effective working temperature of glass columns up to 350°C. Pye gas chromatographs are easy to use because we design them to give you what you want in instrumentation – accuracy, reproducibility, flexibility, simplicity. Two systems are available, both with a wide range of optional modules—
The Pye Series 104 Chromatograph for research or routine work, with many

accessories including wide-range amplifier and auto-solids injection ... and the Pye Model R Research Chromatograph with modular column oven, unique "total-loss" cooling system and simultaneous two column multi-detector operation.

To learn more about Pye chromatography including industrial instrumentation, the GM60 Gas Chromatograph-Mass Spectrometer system and the DP90 Datacon computerised chromatograph system, write or 'phone today.

that you may have missed these important medical titles

ONCOGENIC VIRUSES—2nd Edition

Completely revised and enlarged

Ludwik Gross, Chief, Cancer Research Unit, Veterans Administration Hospital, Bronx, New York.

"... a most valuable source-book". *Lancet*

"... provides a fascinating historical perspective". *Nature*
Reviews tumours known to be caused by oncogenic viruses and discusses the current status of the experimental approach to neoplasms presumably caused by oncogenic viruses in animals and in humans.

994 pages £12 10s hard cover

PROGRESS IN BIOPHYSICS AND MOLECULAR BIOLOGY, Volume 21

Edited by **J. A. V. Butler**, Emeritus Professor of Physical Chemistry, University of London, and **D. Noble**, Balliol College, Oxford

Partial Contents: Ionic Channels in Nerve Membranes—*Hille*; Mechanism of Transmitter Release—*Hubbard*; The Evolution of Bioenergetic Processes—*Broda*; Structure and Evolution of Immunoglobulins—*Milstein and Pink*; The Geometry of Nucleic Acids—*Arnott*.

416 pages £7 10s hard cover

PROTIDES OF THE BIOLOGICAL FLUIDS

Edited by **H. Peeters**, Director of the Simon Stevin Institute for Scientific Research, Brugge, Belgium.

Proceedings of the Seventeenth Colloquium, Brugge, 1969

Contents: (Section Headings): Academic Lecture; Genetics of the Antibody Response; Molecular Variation; Electro-fusing; Techniques.

554 pages £7 hard cover

FAT-SOLUBLE VITAMINS

Edited by **R. A. Morton**

Partial Contents: Chemical Structure and Physical Properties; The Chemistry of Vision; The Biochemistry of Vitamin A in the General System; Human Nutrition in Respect of Fat-Soluble Vitamins.

366 pages £6 hard cover

International Encyclopaedia of Food and Nutrition, Volume 9

PHARMACOLOGY OF THE ENDOCRINE SYSTEM AND RELATED DRUGS: Parathyroid Hormone, Thyro-calcitonin and Related Drugs

H. Rasmussen

Provides a presentation of the biochemistry, physiology and pharmacology of those agents which are most germane to the field of parathyroid hormone.

352 pages £6 hard cover

International Encyclopedia of Pharmacology and Therapeutics, Section 51

ASSAY OF PROTEIN AND POLYPEPTIDE HORMONES

H. Van Cauwenberge, Professor of Internal Medicine and Medical Pathology, University of Liège, and **P. Franchimont**, Agrégé, Director, Radioimmunoassay Laboratory, University of Liège

A review of the current status of radioimmunological assay methods for protein and polypeptide hormones.

244 pages £5 hard cover

International Series of Monographs in Pure and Applied Biology Modern Trends in Physiological Sciences, Volume 33

BEHAVIOUR STUDIES IN PSYCHIATRY

Edited by **S. J. Hutt** and **Corinne Hutt**

A symposium by research workers in the field of behavioural studies whose orientation is towards ethnological techniques applied to the study of the mentally ill, suggesting a new line of enquiry in psychiatric research.

228 pages 50s hard cover

RESIDENTIAL CARE FOR THE MENTALLY RETARDED

Edited by **Elspeth Stephen**, Principal Psychologist, Queen Mary Hospital for Children, Carshalton

Papers illustrating applications of social science to medicine, which go beyond diagnosis on assessment and begin to study processes and the factors which influence them. Concern themselves with quality as well as type of care and direct attention to problems of central importance to the functioning of services.

56 pages 15s flexi-cover

Symposia Series published for Institute for Research into Mental Retardation

Inorganic Macromolecules Reviews

The Chemistry, Physics and Technology of
Macromolecular Inorganic Compounds and Materials

Editors: F.G.R. Gimblett (London, Great Britain)
K.A. Hodd (London, Great Britain)

Supplementing present studies of inorganic macromolecular systems, reported in a variety of journals, INORGANIC MACROMOLECULES REVIEWS provides a medium in which important aspects and developments of these studies are presented as a whole.

Inorganic macromolecules are interpreted broadly to embrace both natural and synthetic systems. Thus the REVIEWS help bridge the gap existing between organic polymer science, glasses and ceramics, and should be of interest to chemists, physicists, polymer scientists, materials scientists and materials engineers working in this field.

The first two issues are devoted to the proceedings of the International Symposium on Inorganic Polymers held in April, 1969 at the Northern Polytechnic, London, and include the following papers:

Inorganic polymers, by L. Holliday, London
Nitrogen-Sulphur compounds, by M. Becke-Goehring, Heidelberg
Polyelemento-organosiloxanes, by K.A. Andrianov, Moscow
Polymer chemistry of boron cluster compounds, by H.A. Schroeder, New Haven, Conn.
Viscoelasticity of inorganic polymers, by A. Eisenberg, Montreal
Equilibria and kinetics in inorganic polymerizations, by J.R. Van Wazer, Nashville, Tenn.
Sulphur-containing polymers, by M. Schmidt, Würzburg
Polymeric metal phosphinates, by B.P. Block, King of Prussia, Pa.
Macromolecular crystals and the Clausius-Clapeyron relation, by H.K. Livingston, Detroit, Mich.
Organometallic coordination polymers involving alkoxo and alkylamido bridges, by D.C. Bradley, London
Some aspects of the vapour growth of ceramic whiskers, by T.J. Lewis, Waltham Abbey

A selection of papers appearing in Volume 1 No. 3

Boron-nitrogen polymers, by I.B. Atkinson, B.R. Currell, Chessington
The structures of orthoboric acid and its thermal decomposition products, by P. Broadhead, G.A. Newman, Harrow
Silarylene and silarylene-siloxane polymers, by W.R. Dunnivant, Columbus, Ohio

Free specimen copies are available to librarians and research workers by writing to the publisher on their institute or company letterheads.

Publication will be in approximately one volume of four issues per year. Subscription price is Dfl. 90.00 plus Dfl. 5.40 postage or equivalent (US\$ 25.00 plus US\$ 1.50 or £ 10.9.6 plus 12s.6d. as at September 15, 1970).

Subscriptions may be placed with your usual supplier or directly with the publisher.

Palaeomagnetism—Data from Jamaican Pliocene agree with those from deep sea cores—ROBINSON (West Indies) and LAMB (Esso)	1236	Brain waves—Hypnotic susceptibility increased by EEG alpha training—ENGSTROM, LONDON (Southern California) and HART (California)	1261
BIOLOGICAL SCIENCES		Inherited tremor—Manifestation in the domestic cat—NORBY and THULINE (Rainier School, Washington)	1262
Polypeptide conformation—Solvent effects on actinomycin, relevant to interaction with DNA—ASCOLI, DE SANTIS and SAVINO (Rome)	1237	Amoeba actin—Methylated amino-acids include ϵ -N-dimethyllysine—WEIHING and KORN (US National Institutes of Health)	1263
—Conformational and NMR analysis of the lactone rings of actinomycin D—CONTI and DE SANTIS (Rome)	1239	Phthalic acid—Large concentration in lipids of jellyfish—MORRIS (National Institute of Oceanography)	1264
Protein homology—Cross-reaction between bovine α -lactalbumin and hen's egg-white lysozyme—STROBERG, NIHOUL-DECONINCK and KANAREK (Brussels)	1241	Variegated plants—When is the male plastome eliminated?—NILSSON-TILLGREN and WETTSTEIN-KNOWLES (Copenhagen)	1265
Brain RNA—Changes in rats undergoing electric shock—GARDNER, DeBOLD, FIRSHEIN and HEERMANS (Wesleyan University, Middletown, Connecticut)	1242	Plant cells—The enzymes in soft rot parasites kill protoplasts—HALL and WOOD (London)	1266
Mammary tumour agent—Unique glycoprotein isolated from mouse milk containing the agent—MIROFF, MEADE, WINETROUT and LAMBERSON (Union College, Schenectady)	1243	Fungicides—Derivatives of fluorene, phenanthrene and xanthene have therapeutic effects on diseases of tomato—BUCHENAUER and GROSSMANN (Justus-Liebig)	1267
Tumour cells—Differential toxicity of concanavalin A towards normal and transformed cells—SHOHAM, INBAR and SACHS (Weizmann Institute)	1244	Plant pathology—New scheme for designating physiological races of pathogens—HABGOOD (Welsh Plant Breeding Station)	1268
Lymphocytes—Cytotoxic cells fail to respond mitotically to phytohaemagglutinin—MacLENNAN and HARDING (Radcliffe Infirmary, Oxford)	1246	Taxonomy—Key generation by computer—PANKHURST (Cambridge)	1269
Blood—Release of elastolytic activity from platelets—ROBERT, SZIGETI, ROBERT (CNRS), LEGRAND, PIGNAUD and CAEN (Hôpital Saint-Louis, Paris)	1248		
Tumour antigens—Solubilization of human leukaemia specific antigens—VIZA, DAVIES (Searle) and HARRIS (Royal Infirmary, Manchester)	1249		
Antigen recognition—By rosette forming cells—BACH, MULLER and DARDENNE (Hôpital Necker, Paris)	1251		

The titles on this page are prepared by the staff of *Nature* on the basis of the titles submitted by authors which appear in full on the pages indicated

ADVANCES IN VETERINARY SCIENCE AND COMPARATIVE MEDICINE

Volume 14

edited by **C. A. BRANDLY**, College of Veterinary Medicine, University of Illinois, Urbana, Illinois, and College of Veterinary Medicine, Kansas State University, Manhattan, Kansas, and **CHARLES E. CORNELIUS**, College of Veterinary Medicine, Kansas State University, Manhattan, Kansas.

November 1970, 438 pp., 205s. (\$22.00)

EXPERIMENTAL NEUTRON RESONANCE SPECTROSCOPY

edited by **J. A. HARVEY**, Oak Ridge National Laboratory, Oak Ridge, Tennessee.

December 1970, about 500 pp., 275s. (\$29.50)

CHEMICAL ZOOLOGY

Volume 5: ARTHROPODA—Part A

edited by **MARCEL FLORKIN**, Department of Biochemistry, University of Liège, Belgium, and **BRADLEY T. SCHEER**, Department of Biology, University of Oregon, Eugene, Oregon.

December 1970, 478 pp., 224s. (\$24.00)

Subscription Price 1971s. (\$20.40)

Subscription Price valid only on orders for the complete set received before publication of the last volume.

BIOLOGY OF BATS

Volumes 1 and 2

edited by **WILLIAM A. WIMSATT**, Division of Biological Sciences, Cornell University, Ithaca, New York.

Volume 1

December 1970, about 390 pp., 233s. (\$25.00)

Subscription Price 1981s. (\$21.25)

Subscription Price valid only on orders for the complete set received before publication of the last volume.

THE CHEMISTRY OF SYNTHETIC DYES

Volume 4

edited by **K. VENKATARAMAN**, National Chemical Laboratory, Poona, India.

February 1971, about 480 pp., in preparation

RELATIVITY RE-EXAMINED

by the late **LEON BRILLOUIN**.

December 1970, 110 pp., 63s. (\$6.75)

PHYSICAL PRINCIPLES AND TECHNIQUES OF PROTEIN CHEMISTRY Part B

edited by **SYDNEY J. LEACH**, Russell Grimwade School of Biochemistry, University of Melbourne, Parkville, Victoria, Australia.

February 1971, about 450 pp., in preparation

EVOLUTION OF PARTICLE PHYSICS

edited by **MARCELLO CONVERSI**.

3Q1970, about 320 pp., in preparation

THE CHEMISTRY OF NONAQUEOUS SOLVENTS

Volume 3:

INERT, APROTIC, and ACIDIC SOLVENTS

edited by **J. J. LAGOWSKI**, Department of Chemistry, University of Texas, Austin, Texas.

December 1970, 416 pp., 196s. (\$21.00)

COMPUTER TECHNIQUES IN IMAGE PROCESSING

by **HARRY C. ANDREWS**, Department of Electrical Engineering, University of Southern California, Los Angeles, California, with contributions by **WILLIAM K. PRATT**, Department of Electrical Engineering, University of Southern California, Los Angeles, Calif., and **KENNETH CASPARI**, ITT Electro Physics Laboratories, Hyattsville, Maryland.

1970, 179 pp., 98s. (\$10.50)

QUATERNARY RESEARCH

An Interdisciplinary Journal

Editor: **A. L. WASHBURN**. Co-Editor: **JOE S. CREAGER**.

Volume 1 (1970-71) 250s. (\$30.00), 4 issues

(Add 12s. 6d. for postage outside U.S.A. and Canada)

Personal Subscription 83s. 4d. (\$10.00)

(Add 12s. 6d. for postage outside U.S.A. and Canada)

Personal subscriptions are available on orders placed directly with the publishers certifying that the subscription is paid for by the subscriber for his personal use.

CURRENT TOPICS IN SURGICAL RESEARCH

Volume 2

edited by **DAVID B. SKINNER**, Department of Surgery, The Johns Hopkins Hospital, and **PAUL A. EBERT**, Department of Surgery, Duke University Medical Center.

1970, 568 pp., 224s. (\$24.00)

Only four controls —but what performance!

Simple to look at . . . just as simple to use.
The new Unicam SP1000 Infrared Spectrophotometer.

Give your new lab technician a few minutes' instruction, and you have an immediate capacity for infrared spectra of the highest quality. You might think, because of all that simplicity, that we have sacrificed something along the way. Just one thing—the price. Everything else is comparable to instruments costing very much more.

How is this possible? For one thing we have introduced a high performance Ebert grating monochromator which gives excellent resolution. Then there is an improved pneumatic detector incorporating solid-state circuitry, and a large (20 cm x 48 cm) integral strip chart recorder for supremely clear results. A full range spectrum ($625\text{--}3800\text{ cm}^{-1}$) will take you just two minutes, or for work of the highest precision press the "slow scan" button and wait less than five and a half minutes.

It will certainly pay you to learn more about the SP1000. Or if your needs are even more demanding then there is the Unicam SP1200. Write or phone today for a free brochure.

Animal behaviour —Can learning really survive metamorphosis?—REYNIERSE (Hope College, Michigan)	1369
—Reply to Reynierse on survival of learning acquired at the larval stage—BORSELLINO, PIERANTONI and SCHIETI-CAVAZZA (CNR)	1370

The titles on this page are prepared by the staff of *Nature* on the basis of the titles submitted by authors which appear in full on the pages indicated

The Astronomy Book of the Year . . . acclaimed by the
'Times' as

"A Universal First"

Atlas of the Earth from Space/Moon Solar System Stars

The publishing event of 1970,
an astonishing British
achievement created in
London by Patrick Moore
with Mitchell Beazley
and George Philip.

"I commend the Atlas of the Universe
. . . based on the most up-to-date
official sources it provides a work of
reference of equal value for the home
and expert . . . will retain its value as a
guide to new discoveries."

Sir Bernard Lovell

"We of the National Aeronautics and
Space Administration are delighted
with the Atlas's beautiful portrayal of
the unlimited challenge of the vast
terrae incognitae in space that is
before us."

Dr. Thomas O. Paine

272 pages/over 1300 illustrations/only
16 pages in black and white - the rest
in up to six colours/15" x 11"/laminated
slip case.

£10.15.0.

September 29th

CROFT PARALLEL GRINDING MACHINE (MOTOR DRIVEN)

For precision grinding of thin sections and fossils

The travelling carriage of the machine moves in a circular track over the grinding plate controlled by steel balls running in precision machined tracks. Mounted in the centre of the carriage is a metric micrometer which houses the specimen holder. When the carriage is in the grinding position as illustrated, the micrometer can be adjusted until the specimen is in contact with the grinding plate, at this point the reading should be taken and then the amount to be ground off should be set on the micrometer. The specimen holder will lift by this amount and as the machine grinds the holder will return to its setting position, which once reached will stop any further grinding of the specimen even if the machine continues to run.

Grinding plates can be supplied in zinc, copper, cast iron, glass or lead.

More Watchdogs in Embryo

If the clamour for a better environment which has been dinning away in the United States for the past several months should yield no tangible result, at least there will be two new arms of the Federal Government as monuments. This, for practical purposes, is the immediate effect of the President's message to Congress on July 9 in which he asked permission—Congress has sixty days to record such dissent as there may be—to set up an Environmental Protection Agency as a separate agency of the Federal Government, and in which he also acceded to the pressures of the past year or so to set up a National Oceanographic and Atmospheric Agency—NOAA to its friends and sponsors—within the Department of Commerce. To begin with, the new agencies will be patchwork affairs, put together from the bits and pieces already in existence. In the long run, everything will depend on whether the two wholes are larger than the sums of their parts. Mr Nixon himself seems to have been well aware of the dangers of creating new departments of state whenever new problems arise, but on this occasion he has explained that the need to treat problems of the pollution of the environment as a connected whole has been overriding. There is some force in this argument, even if the physical unity of environmental pollution is not nearly as evident as Mr Nixon said. There is no necessary connexion between the monitoring and control of sulphur dioxide in the atmosphere and of sewage in the rivers, for example, but there may well be great benefits in lumping together the people who will have to be worrying about the principles on which standards for the control of both kinds of pollution are worked out.

More promising but further away, there is the possibility that those responsible for enforcing standards will gather strength by having to battle shoulder to shoulder against the vandals, for this is the sense in which the machinery of government in the United States is most grievously deficient. None of these things will happen spontaneously, however. The President's message is much that of a man who has assembled a model aircraft out of a kit of parts and who is now waiting—anxiously, it is to be hoped—to see whether it will fly. Unhappily, the United States has too long a tradition of meeting crisis by the creation of an agency for success to be assured, and there is always the danger that the concentration of responsibility for the environment in a single agency will seem to other branches of the Federal Government to be a licence to forget all about the need to look out for the environment. If the environment is indivisible, it is also by definition ubiquitous, and time may yet show that the President would have been wiser to

devise machinery for making the more feckless agencies act responsibly than to rob agencies such as the Department of the Interior and the Department of Health, Education and Welfare of those functions which already make it rub their noses in the environment, so to speak. Time will tell, but the success is neither automatic nor—on precedent—likely.

The President has not gone out of his way to make sure that the new agency will be sufficiently well endowed to carry weight in Washington—even his friends will admit that. Why, for example, should the new environmental agency be given that part of the Food and Drug Administration which is responsible for setting standards for the regulation of pesticides, but not that which controls food additives? (That remains with the FDA where it has been since the early fifties.) No doubt there are those who will argue that such a course will help to avoid fiascos such as that earlier this year in which the FDA and the Department of Agriculture took opposing views on the safety of the herbicide 2,4,5-T, but they can be assured that the next muddle will be different from that. The plain truth is that if the unity of the problem of environmental control is as real as Mr Nixon makes out, there is very little excuse for not having transferred the whole of the FDA to the new agency. And what of the Geological Survey, with its present responsibility within the Department of the Interior for offshore drilling and pipelines across Alaska as well as for a proper classification of the Ordovician and the like?

The Ash Commission on Government Reorganization which has provided the framework for Mr Nixon's proposals seems to have argued for an even larger rag-bag of functions, and there is certainly a danger that, as things are, the new agency will find that it represents too small a proportion of its potential scope to be viable in the cut-throat competition not merely for funds but for leverage which occupies much of the Washington calendar. As a piece of administration by reshuffling, therefore, the best thing to be said of the new proposal is that it removes from the Atomic Energy Commission responsibility for regulating the manner in which radioactivity is released to the environment from nuclear power stations. Although there is no reason to think that the AEC has been worse than smug in its handling of these matters, it is better that the functions of judge and jury should be separated from each other. In short, there is enough doubt about the good sense of the proposed arrangements for a congressional inquiry—even a benevolent inquiry—to be a public service. It is to be hoped that sixty days will not pass entirely in silence.

Important questions about the regulatory powers of

the new organization also cry out to be answered. In spite of all the frenzy of the great campaign against pollution, the plain truth remains that the most serious difficulty in the United States is that of arranging that the aspirations of the Federal Government will be translated into action by state and municipal authorities. It is only natural that even the most vigorous advocates of a better environment should be ill-disposed towards higher taxes, but the result is usually an unfortunate separation of the analysis of problems and responsibility for their solution. This, for example, is why it is more than likely that Mr Nixon's own trumpeted programme for the abatement of water pollution, the pride of February, is now likely to seem like an ironical demonstration that the nation that won an international reputation for its domestic hygiene in the thirties is now incapable of preventing itself from using rivers as sewers, \$4,000 million of federal money notwithstanding. There is nothing in the President's message to suggest that the Environmental Protection Agency will be better able than, say, the National Air Pollution Control Administration which, in its present incarnation, has had remarkable success in winning motor car manufacturers to its way

of thinking but which has not been able to rid the United States of noisome air except in places where people do not congregate. A part of the trouble, of course, is that the control of pollution is an even hotter potato than anxiety about the environment, and that no federal government is ever likely to delegate to a separate agency responsibilities which might cut across the existing lines of demarcation between central and regional authority.

Congress, which is likely to applaud the new proposals, would certainly turn nasty if the Administration went too far in its assumption of power to regulate. The result of this tacit agreement not to give mutual offence, however, is that the embryo tiger will have no teeth until somebody manages to rob regional public authorities of their traditional right to create a public nuisance (or several) if their taxpayers choose. That, of course, is a political problem. It is no disrespect to say that the President has ducked it this time round. None of his predecessors has had much relish for it either, yet it is a cruel irony that neglect of this central problem should not be regarded as a disqualification of declarations of good intentions on the environment.

Government by Committee

IN the memorable words of Mr Harold Wilson about the opinion polls before the last election, the new leader of the new House of Commons, Mr William Whitelaw, failed to distinguish himself in his statement on the future of the select committees on July 9. The particular blend of cockiness and silliness with which he assured his colleagues that "we must avoid developments which will lead to a position like that reached in the United States Congress, where committees are all-important" may be attributed to the unexpected novelty of his present responsibilities. The consequences could, however, be unfortunate (see page 217). The occasion for Mr Whitelaw's declaration is the need to respond to the suggestions which the Select Committee on Procedure has made about the organization of parliamentary business, and it is at least creditable that he should wish to say something. The signs are, however, that the leader of the House of Commons is not entirely clear in his own mind what the House of Commons is meant to accomplish. And for all his assurance that the hard work of the Select Committee of Science and Technology will not be wasted in any reorganization there may be, he seems sadly to have misunderstood the value of what this and other committees have been doing in the past few years. It is to be hoped that his friends will disabuse him of his error before too much damage has been done.

To begin with, it is grievously mistaken to suppose that the function of legislative bodies such as the House of Commons is largely to engage in debate. In Britain, it is indeed notoriously the case that debates on important issues are occasions on which two oppos-

ing sides can state opposing and usually familiar points of view. Rarely is one of the debates after which Mr Whitelaw hankers likely to produce a result which cannot be predicted. For all his scorn of the United States Congress, this is a matter on which the Senate at least has an obvious edge, as the passing of the Cooper-Church Amendment (right or wrong) must demonstrate. The formal proceedings of the House of Commons are most constructive when some knowledgeable member is able to suggest how the government of the day might better its intentions—even if the minister does not listen, his civil servants will. But the House of Commons is much less good than it should be at keeping up informed and possibly constructive commentary on government policy. The trouble, of course, is that informed questioning of policy in some narrow area requires a degree of application which is usually beyond the scope of the randomly assorted membership of the House of Commons. The result is that on technical matters—not necessarily in science and technology—the House of Commons is less effective than it should be at uncovering and understanding the reasons why governments embark on particular courses of action. Wise leaders of the House of Commons would recognize that, in the long run, governments as well as oppositions are the losers.

A few illustrations taken from the record of the Select Committee on Science and Technology should be enough to convince Mr Whitelaw of the truth of that. The first investigation which the committee carried out led to a much better public understanding of the difficulties to be surmounted in transferring to private

industry public control of all the details of reactor development, even though its own policy recommendation (for an even more powerful central control of development policy) was something of a joke. The fact that the previous government muffed the reorganization is also beside the point (and it is probably significant that neither the Government nor the Opposition thought fit to refer to this hanging problem in the debate on the Queen's Speech last week). The value of the investigation was to have brought into the open a great deal of information that would otherwise have remained buried. Although the process is probably educative of governments, its more immediate

value is in the analysis which it provides for outside interest in their relationships with government. The point is more better illustrated than in the investigation of carbon fibre technology, in the course of which the old select committee made several industrial companies think hard about their intentions in this potentially important field. The fact that the select committee's efforts to uncover the skeletons in the cupboard of defence research have been comparatively ineffective—this was one of the more solid reports—is best explained by the indifference of government and taxpayers alike to the important issues which are involved.

Monsters and Poltergeists

1969 was a poor year for the Loch Ness Phenomena Investigation Bureau Limited. Only fourteen "acceptable" sightings were made, according to the Bureau's annual report, three of them supported by film. This is a miserably poor tally compared with the reports of flying saucers received by Project Blue Book of the US Air Force, which handled some 10,000 sightings in less than 20 years, an average of about 15 flying saucers a day. What is more, some 5 per cent of the American population believes they have seen a flying saucer, whereas professed belief in the Loch Ness monster is probably strongest among those with stakes in the Scottish tourist trade. Nonetheless, there are signs that the managers of the monster's affairs are beginning to learn the basic rudiments of their business, in which case sightings of the monster can be expected to become a more regular feature of the summer season.

Those who peddle the monster face disaster on two sides but are safe as long as they tread a middle path. One calamity would be if a particularly rigorous search of Loch Ness should prove that no monster exists. The other would be if some natural explanation for the sightings were actually to be found, since it would certainly fail to live up to the expectation of a pleio-saurian creature such as that portrayed on the annual report of the Loch Ness Phenomena Investigation Bureau Limited. The keepers of the faith are probably guarded quite well against these heresies. Loch Ness has been searched for more than a decade without any shred of monster coming to light, but this, of course, merely enhances the mystery, and no search, however meticulous its operation and sound its sonar, can easily prove a negative. Moreover, the Loch Ness Investigation Bureau Limited has shown its excellent sense of survival by undertaking not to capture or lay hand on the monster—the most it will do is take a tissue sample. Concern for a unique specimen is, of course, admirable, but even more credulous ages than this would have looked askance at somebody who went out to prove unicorns exist but vowed not to catch one. The other danger is that the monster may be found, and, if it be but a large eel or schoolboy prankster, fail to come up to expectation, but the

crisis could doubtless be met by an unflinching denial that this was the True Monster.

The True Monster, indeed, is likely to flourish in the years to come since its one vital pabulum is publicity, and its handlers are becoming increasingly adept at procuring this evanescent diet in the right quantities. No less than the Minotaur, the Loch Ness Monster thrives even on unfavourable publicity—this year's report quotes in full a recent article (*Nature*, 220, 1272; 1968) that criticized the monster's cognitive status, together, of course, with a line for line rebuttal. Indeed, the monster is now doing so well that even that sober newspaper, the *Financial Times*, greeted the Loch Ness Bureau's annual report with the headline, "Evidence of loch creature grows". The inhabitants of the Loch Morar district, for their part, have decided to exploit the monstrous atmosphere created by their neighbours at Loch Ness and earlier this month it was announced that Loch Morar, too, would be screened for a monster, already christened, with suitably Tolkienesque undertones, as Morag. The sponsors of the Loch Morar survey stated that the monster hunt would be a contribution to European Conservation Year, but it is hard to say whether the thought of conserving an animal that is almost certainly non-existent is intended as an elaborate satire on the conservation movement or a simple leg pull of the rivals at Loch Ness. It should not be long before Unidentified Swimming Objects are sighted in the Scottish lochs as regularly as the reports of UFOs in the United States that swamp any agency prepared to listen to them.

The triumphal progress of the Loch Ness and Morar monsters makes an interesting contrast with another attempt to investigate phenomena which most reasonable men would probably consider illusory. The Society for Psychical Research, founded in 1882, is now approaching a century of investigations into the occult without having yet produced any unassailable and repeatable evidence of extra-sensory perception, psychical phenomena or life beyond the grave. There is, however, a world of difference between the Society for Psychical Research and organizations like the Loch Ness Bureau of Investigation Limited.

Subject matter apart, the society practises a methodology of investigation which is not seriously different from that of the more successful natural sciences. The journal of the society, for example, contains sober accounts of experiments designed to falsify various hypotheses about psychical phenomena. Some of these accounts inspire sympathy, such as that of an attempt to detect psychical effects in protozoa (by willing them to move in particular directions) which concludes: "The writer did not embark on these experiments in an attitude of disbelief; on the contrary, he fully expected to obtain positive confirmation of the Richmond effect and was somewhat disappointed when he failed to do so" (*Journal of the Society for Psychical Research*, 45, 296; 1970). This report, however little surprise it may occasion, belongs to science no less than do statements such as: "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material." The language of the Loch Ness monster hunters, on the other hand, has nothing to do with science. Their experiments may be conducted with every modern piece of scientific apparatus that publicity requires, but because the methodology is deficient, the pursuit of the Loch Ness monster is no more a scientific endeavour than the hunting of the snark. That is why even poltergeists are scientifically more respectable than the Loch Ness monster.

100 Years Ago

Spontaneous Generation

DR. H. C. BASTIAX, who has recently called attention to the nature of the evidence before scientific men in favour of the theory of so-called spontaneous generation, has supplemented it by fresh experiments of his own. The dilemma in which the opponents of this doctrine are now placed is that they must either admit it, or else allow that a temperature of 150° C. maintained for four hours, and applied by means of liquid, is incapable of killing the germs of infusoria. Many, doubtless, of these opponents will courageously mount this horn of the dilemma, and make the requisite enlargement of their ideas on the subject of vital resistance to change. There are, however, other difficulties in the way. For instance, great difficulties are involved in the assumption that the atmosphere constitutes a storehouse of germs of all kinds ready to burst out into life on the occurrence of suitable conditions.

However small these germs may be, still they must weigh something. And there must be very many of them, seeing that there must be an immense number of kinds of germs, if a volume of air is to supply to any given infusion precisely the right kinds of germs suitable to the conditions provided by the infusion.

Now chemists are in possession of data showing that the possible amount of organic nitrogenous matter in common clear water and common good air is remarkably small—so small, indeed, that the question may fairly be asked—Is it large enough to admit of the requisite number of germs, the existence of which the vitalists assume in water and air?

From *Nature*, 2, 234, July 21, 1870.

OLD WORLD

INVENTIONS

New Broom for Patent Office

A THOUSAND patent applications are filed at the British Patent Office in an average week. Even so, the office is not yet so overloaded that it has had to follow the example of its counterparts in Holland and Germany which now defer the examination of applications as a matter of course. Nevertheless, something must be done as quickly as possible if a similar system is not to be introduced here. Patent applications are not published until they are accepted, and the delay can be up to four years from the date of filing. Even then the Patent Office is only able to carry out a comparatively limited search and examination so that the likelihood of the patent being invalid is higher than it ought to be. If legal proceedings are involved they can be protracted, causing more delay and uncertainty. This is the scene facing a committee that for the past three years has been looking at the patent system and which reported this week (*The British Patent System*, HMSO, £1 15s). Patents will become harder to get if the recommendations of the report are implemented.

The situation is becoming so drastic that patent offices are being driven to cooperate with each other. Last month Britain and nineteen other countries signed the Patent Cooperation Treaty in Washington, which establishes at least five centres to which the national offices can send patent applications for a report on novelty. This still leaves the granting of a patent to the national office, but a more revolutionary scheme under discussion is for a European Patent Office granting patents that would be valid in eighteen European countries (see *Nature*, 226, 888; 1970).

It will be several years before international cooperation becomes effective, and in the meantime the service given by the British Patent Office is becoming poorer. In the opinion of the committee, too many unnecessary patents are being granted, for example, because the patent office works on the principle of giving an application the benefit of the doubt if there is any chance of it coming under the Patent Acts. In future the committee would like to see the office have stronger powers to reject applications. To make patents more valuable the search and examination procedures ought to be tightened up, and the fees ought to be higher both to help cover costs and to discourage applicants who lose interest in their applications. Because of the delay in granting patents the committee would like to see the specification published 18 months after the claimed priority date, together with the search report. The applicant would then have to pay if he wanted to continue.

The committee is unusual in having an industrialist as chairman, Mr M. A. L. Banks, now chairman of Cammell Laird, rather than a member of the legal profession. Mr Banks sees the present state of affairs of the patent system as the steady deterioration of a valuable incentive scheme for industry. Mr Banks is also concerned about the conditions under which the patent officers work. The patent office in Chancery Lane has to be seen to be believed, he says, and examining staff are now accommodated in five different buildings. A new building for the patent office, which must be near the

National Reference Library of Science and Invention, is a matter of urgency.

Mr Banks is not unduly worried that the recommendations of his committee will make life harder for the rare private inventor. It seems that the cheap fees that they enjoy—British patent office fees are relatively low—will have to be sacrificed if the system is to be at all efficient. But the committee calls for the Department of Employment and Productivity to encourage the voluntary schemes by which firms reward employee inventors.

PARLIAMENT

Axe over Science Committee

THE wings of some of the select committees set up by the Labour Government are likely to be clipped and some committees, including the Select Committee on Science and Technology, may disappear altogether. These will be casualties of what the Leader of the House of Commons, Mr William Whitelaw, described last week as his desire to see the floor of the House of Commons as the centre of Parliament—the place where “true debate must take place”—and their demise will be part of an attempt to prevent the British system of government going the same way as the United States Congress in moving towards what is effectively government by committee.

Mr Whitelaw announced during his winding up of the debate on the Queen's speech that he intends to publish a Green Paper in the autumn setting out proposals for the future of the select committee system. He is expected to take up the suggestion of the Select Committee on Procedure that a select committee on public expenditure and administration should take over some of the functions of the select committees on nationalized industries, science and technology and estimates, and these committees will not be reconstituted. What will happen to the Select Committee on Education and Science which, like the Select Committee on Science and Technology, was caught by the election in the middle of an enquiry, is less certain.

A broad hint that the Select Committee on Science and Technology is likely to be dropped is Mr Whitelaw's assurance that all the hard and valuable work done by the select committees last session will be made available to whatever committee system the House of Commons eventually adopts. If this means that the evidence taken by the subcommittee enquiring into the computer industry will be available to some new select committee next year, then it is unlikely that the enquiry will ever end up as a report to Parliament because the evidence is likely to be out of date by the time any new enquiry gets under way. The evidence taken by the Select Committee on Education and Science is, however, more readily usable because its enquiry into teacher training will be carried on by the Royal Commission on Teacher Education which was announced in the Queen's speech.

It is ironic that Mr Whitelaw's avowed intention to transfer debate from committee rooms to the floor of the House will in fact mean that science and technology will receive even less attention in Westminster than they do at present. The removal of many scientists and technologists from the corridors of power by the election has left the House of Commons desper-

ately short of people interested in scientific affairs, and the Select Committee on Science and Technology at least brought Parliament's attention to some problems concerned with the development of technology. The committee, for example, has managed to focus considerable attention, both inside the House of Commons and elsewhere, on the structure of Britain's nuclear industry and on the potential for development of carbon fibres. Its enquiry into the structure of the computer industry had already aroused considerable interest among computer manufacturers and others. Although a decision to scrap the select committee will be in line with Conservative policy to “liberate” industry from government interference, it will be a pity if that decision also reduces the level of scientific debate in the House of Commons.

COMPETITIONS

Maths Marathon

ABOUT 100 young mathematicians have been competing in Budapest this week for honours in the Twelfth International Mathematical Olympiad. After surviving some very tricky courses in their home countries, they have been battling it out over two four-hour written marathons in which they have been awarded extra points for style and for taking shorter routes than their opponents. The contestants have been going for national as well as personal honours.

The national teams, each consisting of eight mathematicians aged under nineteen and a half, were all invited to take part by the Hungarian Government. It is the prerogative of the host country to choose which countries to invite and until four years ago, when the Olympiad was held in Yugoslavia, no Western country was asked to take part. This year, several Western European countries have been invited.

The British team was selected by the Committee for Mathematical Awards of the Mathematical Association, from a field of between 15,000 and 18,000 entrants. All contestants took part in the heats—an examination set by the Committee for Mathematical Awards—and the seventy who fared best were invited to take part in the British Mathematical Olympiad. This is a written event over a lengthy course similar to that of the international competition. Those who completed the questions with the most style and taking as few steps as possible were given the opportunity of representing their country in the International Olympiad. A British team has competed in three previous competitions and each time it has come fourth after Hungary, East Germany and the Soviet Union.

The International Olympiad consists of two four-hour papers set jointly by the countries taking part. Contestants have to answer three questions in each paper; for example, “Prove that there exists a unique triangle whose sides are consecutive real numbers and one angle of which is twice as large as another” (1968 Olympiad). Special prizes are awarded for particularly elegant solutions to some of the problems. The British team consists of Bernard Silverman (City of London School), Jonathan Edwards (Royal GS, Newcastle), Stuart Bell (Dartford GS), Charles Batty (Rugby School), John Proctor (Queen Mary School, Walsall), John Segal (Dulwich College), Stephen Furber (Manchester GS) and David Grubb (Greenford GS).

STRUCTURAL ENGINEERING

Test for Tower Power

WITH the supply of pylons for electricity transmission becoming an increasingly cut-throat business where every pound of weight saved counts, an optimistic future for the National Tower Testing Station was predicted by its manager, Mr W. R. Box, last week. If nothing else, the station wins the prize for being the most bizarre laboratory in Britain. A stone's throw from Cheddar Gorge, the station's asset is a disused limestone quarry which happened to be just the right shape and a collection of hydraulic rams dotted around the floor and face of the quarry. To simulate the working conditions of the pylons—conductors covered with ice, and so on—the rams, by working backwards, exert known loads on ropes attached to the structure. But the science involved is more than the parallelogram of forces. From a control room perched above one face of the quarry Mr Box and his colleagues run a sophisticated system which controls the rams and measures the applied loads to one per cent.

The National Tower Testing Station. Some of the rams are enclosed in the shed on the far face of the quarry.

Established by the Central Electricity Generating Board in 1966, the station is not yet making a profit, but it is now covering operating costs and expects to be completely self-supporting by March 1973. Pylons for use overseas occupy about sixty per cent of the work of the station, divided half and half between pylons designed by British companies for export and pylons designed by overseas firms. A pylon designed in Stockholm for use in Pakistan was being erected on the test pad last week. Pylons for use in Britain are going to be in the minority until a new range of towers is instituted.

Although Mr Box and his staff would like to get their hands on all kinds of structures, it looks like the testing of electricity transmission pylons will be taking up most of their time for the next five years or so. Where the tendency has been to overdesign these towers in the past, designers are now paring down the quantity of steel to go after the lucrative contracts in the developing countries of Africa and South America. Competition is fierce and with transmission lines several hundred miles long contracts are won or lost on quite small savings on cost per tower. Towers have to be

tested by law, and designers can send their towers to the National Tower Testing Station where the various disasters which can happen such as icing or an uneven load due to a broken conductor are simulated. Once a tower has been shown to live up to its specification, the designer likes to see by how much he has overdesigned it, and about fifty per cent of the towers are eventually tested to destruction.

ENVIRONMENT

Last Year's Dirty Water

OIL spillages in Britain's coastal waters, both accidental and deliberate, were worse last year than ever before. This is the gloomy news reported by the Advisory Committee on Oil Pollution of the Sea, a body which consists of representatives of the voluntary associations and other British organizations interested in marine use and conservation (report available from 1 Dorset Buildings, Salisbury Square, London EC4). Most of the oil washed up along the coastline came from unidentified sources, and the actions of unscrupulous skippers can only have been encouraged further by the absurdly small penalties imposed after conviction for illegally discharging oil—the average fine for the year was just over £225.

A tougher line with offenders is now promised by the Oil in Navigable Waters Bill, which the new government has taken over. But there are still accidents which damage wild life, and the advisory committee has set up a research unit at the University of Newcastle upon Tyne to investigate the effects of oil on seabirds. The unit is concentrating on the rehabilitation of oiled birds, but difficulties so far have meant that killing the birds remains the recommended policy. In any event, it seems that the worst oil spillages are more likely to kill birds outright—a single episode off the Dutch coast in February, for example, caused at least 20,000 deaths, chiefly of scoters and eider ducks.

Fatalities from other causes, however, were even more serious during 1969. The Royal Society for the Protection of Birds reports that nearly half the breeding population of guillemots in the Irish Sea have not returned to their cliff ledges this year, and suggests that some 50,000 may have died. About 14,000 razorbills also seem to have been lost. Although some birds may be coming back late after wintering in the open sea, these figures may well be the aftermath of the baffling appearance last autumn of thousands of dead seabirds on the shores of the Irish Sea (see *Nature*, 224, 402; 1969). Since in general only about a quarter to a fifth of birds that die at sea are washed up on the land, the 15,000 known deaths correspond fairly closely to the depletions in the breeding population. What killed the birds will probably remain a mystery—suggested explanations such as disease or unusually prolonged gales or contamination with polychlorinated biphenyls all seem insufficient to account for its scale—but the final word must await the publication in a few weeks' time of a report by the Natural Environment Research Council, which coordinated the subsequent investigations.

Polluted water inland is put into less foreboding perspective by the report of the Water Pollution Research Laboratory for 1969 (HMSO, London;

17s 6d), in which work to improve the quality of effluents complements studies of the effects of pollutants. One of the biggest projects is a study of the notorious River Trent, with the aim of finding ways to get the water cleaner without driving to ruin the industries which at present tend to treat the river as an open sewer. The chief need here is to provide by the end of the century for the extraction of 500 million gallons a day of drinkable water at Nottingham. The laboratory is also looking at the recovery of pure water from effluents; one of the most promising techniques under development involves a reverse osmosis process, which should be incorporated in a pilot plant next year.

PRODUCTIVITY

Is Your Lab Well Cited?

CALCULATING the efficiency of a laboratory is a difficult business, especially if the research is too fundamental for technological spin-off to be immediately important. A crude approach is to measure the rate at which the staff publish papers, but this method would not distinguish between the fluency of genius and the loud noises of empty vessels. An attempt to measure instead the quality of a laboratory's publications has now been made by J. Larabi of the French Centre National d'Etudes Spatiales. His method, described in *Le Progrès Scientifique* (No. 137, 1970), is to count up the number of citations that the publications have received in other people's papers.

The first application of the method has sorted out six French space laboratories into a pecking order of productivity, covering the period from 1961 to 1968. An obvious difficulty in assessing the later years is that not enough time has passed for many people to have published their references to the most recent papers. After much poring over the *Science Citations Index*, Dr Larabi has discovered what seems to be a law of propagation of scientific literature: that the rate at which a paper is cited reaches a maximum about two years after the paper is published, and that the distribution of citations through time follows the same pattern for most papers. With this as a guide, he was able to adjust the number of citations for each year to take account of those which may be expected to appear in the next few years.

Four of the laboratories immediately dropped out of the race, references to their output being relatively few and far between. That left the Laboratoire d'Aéronomie and the Groupe de Recherches Ionosphériques, of which the latter emerged as top dog in

every year except 1964 (see table). Dr Larabi emphasizes that his technique is only in its early stages, but he is now working on a cost-benefit analysis with citations as its basis, and expects to be able to surmount the awkward fact that the money spent on research in one year may be related to publications appearing several years later.

DIESEL ENGINES

Rolls-Royce Comes Clean

ROLLS-ROYCE has spelt out its claim to a larger share of the diesel engine market by becoming the first company to produce an engine to comply with the stiff antipollution regulations set out by the British Standards Institution nearly three years ago. Having entered diesel engine manufacture seriously in 1966, Rolls-Royce is hoping that the BSI stamp of approval for the mark 2 version of its 12 litre Eagle 200 engine will prove a timely fillip for its drive to capture important sectors of the market for large engines, particularly for trucks of 30 tons and over.

Apart from a series of exacting tests on vehicle performance, the BSI regulations include a strict limitation on the amount of carbon and solid matter permitted in exhaust fumes. Carbon concentration has been found to vary inversely as the square root of the gas flow, and the BSI standard is the first to incorporate a carbon limit in its demands. One of the casualties of the election has been the abandonment of a White Paper being prepared by the last government which sought to introduce smoke and noise tests into the compulsory examination which heavy goods vehicles have to undergo each year.

Rolls-Royce has made several changes in the design of the 200 h.p. Eagle engine to meet the requirements of the BSI standard. A new piston arrangement has been devised, incorporating three piston rings instead of four, and the whole engine is considerably lighter than the previous model. Production of the Eagle engine is already twice what it was only three years ago, and Rolls-Royce must be hoping that the new government will prove to be as devoted to antipollution legislation as was its predecessor. But it is still too early to know whether or not Mr Crosland's plans to curb pollution from diesel exhausts, as spelled out in the White Paper on the environment published just before the election, will prove to be yet another casualty of the change of government.

British diesel manufacturers selling abroad face lighter antipollution regulations than those laid down by the BSI. In the United States, diesel vehicles have to pass very stringent mechanical tests but there is as yet no ruling on carbon emission from exhausts. On the continent of Europe, there is also no test for carbon emission from diesel engines, but the EEC countries are now considering new proposals which are much on the lines of the BSI standard.

Legislation to limit the noise from heavy vehicles came into effect in Britain on April 1 this year, and brought the maximum permitted curbside level down from 92 dB to 89 dB. Further reductions were outlined in Mr Crosland's White Paper, including the long-term aim of cutting levels for lorries down to 80 dB and for cars to 75 dB. A reduction of 10 dB on this scale means a drop of 50 per cent in the noise which people

THE TOP TWO LABORATORIES: CITATIONS FOR EACH YEAR'S PUBLICATIONS FROM 1962, CORRECTED TO INCLUDE CITATIONS EXPECTED IN THE FUTURE

Year of publication	Number of citations in 16 selected journals Laboratoire d'Aéronomie	Groupe de Recherches Ionosphériques
1962	13	37
1963	25	42
1964	38	28
1965	40	61
1966	45	67
1967	32	78
1968	26	40

subjectively experience. The BSI regulations, which were devised at the instigation of the Ministry of Technology and Industry, make no mention of noise levels, but there will be renewed pressure now on all manufacturers to tailor their engines to the requirements of the BSI certificate.

SOVIET UNION

Problems of Application

from our Soviet Correspondent

IN the past few years there have been frequent announcements in the Soviet press of the opening of scientific institutes and research centres throughout the length and breadth of the Union. While some of these are academic "giants", many of them are relatively small units, with their research slanted at some specific local problem or development. The place of these smaller institutes in the overall picture of Soviet science, and the special planning problems which they pose, has recently been raised by the director of one such institute, I. Evgen'ev, of the Byelorussian Highway Research Institute (*Pravda*, July 7, 1970).

In Byelorussia, for example (the third largest of the Union Republics), more than half the scientific organizations number less than 200 workers. Mostly they are local institutes financed by the relevant ministries and government departments of industry, agriculture and civil engineering. A ministry tends to consider dependent institutes as "its own property", but the support which it gives them, says Evgen'ev, is "not bad at all".

A distinctive feature of these local branch institutes is the absence of any intermediate body between them and the industry they serve. The result of their activity is the implementation in practice of the results of research. In particular, they are very frequently the means by which the basic research carried out in the institutes of the Academies of Sciences and other top level institutes really get a start in life. In the Highway Research Institute, for example, only 60 per cent of the scientific staff are engaged on their own research, and the remainder are engaged in applying it. But the highly specialized nature of these small institutes is, it would seem, posing a number of administrative problems.

The planners, says Evgen'ev, approach all institutes in an identical manner, be they academic giants or small branch institutes. Expenditure and the wages bill are fixed according to the research plan, which usually forms a part of the plan laid down by the government of the republic. All other activity, including the introduction of new results into industry, is "uncoordinated science" and must be financed by the department concerned. Thus there are two plans of operation, the governmental and the departmental and, in the case of small institutes in particular, this can lead to considerable practical difficulties. Furthermore, considerable losses are often involved in the practice by which more than half the work carried out by such institutes is supported by a system of economic contracts. Under these contracts, the ministry's plan not only determines the customers but also guarantees the contract price from a centralized fund. Thus the R and D carried out by the institute is

no longer necessarily conducted on a profitable or self-supporting basis. A better scheme, it is suggested, would be that the central authorities should continue to support basic research, but that all R and D contracts should be settled between the institutes and the enterprises concerned. Only thus would the unique R and D services which these institutes can offer be seen in their proper economic setting.

The proposals which come just before the Party Conference at which top level planning for the next five years will be decided are, in short, a demand that the minor institutes of the Soviet Union, which so far seem to have been held back from operating at their optimum capacity or efficiency, should be better integrated into the R and D system.

UNIVERSITIES

Expansion with Equality

by our Education Correspondent

THE government was given a forceful reminder last week of the problems it must soon tackle in the higher education sector. The Association of University Teachers, which is wholeheartedly committed to university expansion but unable to offer many solutions to the evergreen problem of how to provide university places for 450,000 students by 1981, has warned the Secretary of State for Education and Science that the government cannot stand on the sidelines of higher education for very long (*Universities in the 1970's*, available from the AUT). The association has sensibly pointed out that the first thing the government should do is to take a look at the higher education sector in its entirety, and to abolish a few of the barriers that have grown up between different institutions. There should be more cooperation between the universities and other institutions, and the association goes so far as to advocate establishing formal links between universities and some colleges of education.

Such proposals have been aired before—even the Committee of Vice-Chancellors and Principals cast an eye on the colleges of education and wondered whether they should be turned into liberal arts colleges associated with individual universities (see *Nature*, 226, 790; 1970). But the AUT goes one step further in calling for an end to the binary system, which it calls "an unnatural creation born of financial illusions". Polytechnics, the association argues, should be able to award their own degrees, and the University Grants Committee should distribute finances not only to universities but also to polytechnics and colleges of education. This would take polytechnics out of the realm of local authorities and would bring all institutions of higher education together under the same roof. Such an arrangement would make for easier planning, and would help to remove some of the "second class" stigma that the AUT believes is attached to the non-university sector of higher education.

But the real problem is, of course, money. The AUT is adamant that the higher education sector can cater for twice as many students in ten years time and still maintain its standards only if sufficient money is made available. And that means that expenditure on the universities must reach 0.9 per cent of gross national product by 1980, compared with 0.65 per cent at

present. Professor W. V. Wallace, of the New University of Ulster and convener of the working party which drew up the report, also said that polytechnics and colleges of education must be given sufficient money to improve their staff/student ratio, and to provide better library and laboratory facilities. Without this, they will always be regarded as second class institutions.

Although the association has not offered the government a blueprint for higher education in the 1970s, it has at least said what it is not prepared to tolerate, and has handed out a few suggestions for saving costs. The AUT believes, for example, that there is some scope for more subject rationalization—"in certain subjects it makes sense to concentrate expensive staff, equipment and books in a few universities from the point of view both of teaching and research". But the AUT will predictably guard with some jealousy the staff/student ratio. Professor Wallace pointed out that universities cannot be expected to maintain their academic standards if the ratio is allowed to deteriorate, and he drew attention to the fact that courses in British universities are much shorter than their counterparts in many other countries.

BRUCELLOSIS

Paying for Clean Cows

MANY more dairy and beef herds in Britain should soon be certified free from brucellosis, an infectious disease which causes spontaneous abortions in cows and undulant fever in man. This, at least, is the hope of Mr James Prior, the Minister of Agriculture, who earlier this week announced a scheme which provides incentives for farmers to banish brucellosis from their herds.

The incentives take the form of additional payments to farmers whose herds are registered as free from brucellosis. They will receive an extra 1½d a gallon for their milk and a supplement of 37s 6d per animal will be added to their hill cow and beef subsidy. The payments are guaranteed for at least five years, by which time Mr Prior hopes that at least half the country's cattle will be "clean". The farmer may find that getting his herd registered is an expensive way of gaining these benefits—no compensation is offered for the infected animals which must be killed, and often new fences and equipment must be bought to keep the herd safe—but once his herd is declared uninfected insurance schemes are available which will make good any loss through reinfection.

Of Britain's 200,000 herds, 17,000 are already certified or qualifying as brucellosis free—a result of a voluntary brucellosis scheme set up in 1967. Since these are mainly large herds they amount to about one sixth of the animals in the national herd. However, it is estimated that another third are either free from or only lightly infected with brucellosis, and it is these that the new scheme hopes to attract. In the autumn of next year a compulsory eradication scheme, carried out on an area by area basis, is to start operating, and Mr Prior hopes that if owners of relatively free herds have come forward in large numbers a reservoir of clean cattle big enough to provide any replacements needed will have been built up.

Parliament in Britain

Queen's Speech

THE debate on the Queen's speech contained little indication that the new Parliament will be any more willing to debate science and technology than was the last. Although there was no mention of scientific affairs in the speech itself, the wide ranging debate that always takes place at the start of a new Parliamentary session gives ample opportunity for members to air their views on such subjects, but only Mr Airey Neave found himself disposed to take the plunge. He put in an impassioned plea for the Select Committee on Science and Technology to be allowed to carry on with its business, and he asked the government not to rush into any decisions about research establishments or to base its industrial research policies on the Green Paper published by the Labour Government. He also asked for the Atomic Energy Authority to be retained as a separate research organization.

On education, Mr Fred Willey, past chairman of the Select Committee on Education and Science, provided welcome relief from the bitter and protracted wrangles over Mrs Thatcher's decision to withdraw the circular requiring local authorities to submit plans for comprehensive secondary education. Mr Willey accused the Labour Government, of which he was a member, of making a "disastrous mistake" in creating a binary system of higher education. He hoped that Mr Van Straubenzee, the new Under Secretary of State in the Department of Education and Science, who was also a member of the select committee, will be able to exert some influence in getting some of the committee's recommendations accepted.

Post-Apollo Programme

MR TAM DALYELL raised the question, in an adjournment debate, of Britain's cooperation with the United States on a space station and space shuttle service. He wanted some indication from the government of its attitude to the offer from NASA of a European share in the post-Apollo programme, and whether the estimate of between 200 and 300 million dollars a year, to be provided on a European collective basis, is unacceptable. Mr David Price, Parliamentary Secretary to the Minister of Technology, said that the European governments concerned will be discussing NASA's invitation at the European Space Conference next week. Although no firm decisions are expected to be taken at the conference, Mr Price said that the British Government believes that there should be a multilateral European response to the policy issues involved, and the conference is expected to lay down formal machinery for handling discussions and eventually negotiations with the US authorities. (Debate, July 10.)

Rolls-Royce

THE government has received revised proposals from Rolls-Royce for a more powerful version of the RB211 engine, and it is considering a request for financial aid to launch the engine. This announcement was made by Mr Geoffrey Rippon, Minister of Technology, in reply to questions from Mr Tam Dalyell and Mr Robert Sheldon, and the minister said that he would make a full statement later. He declined to say whether such aid would be considered unnecessary interference by government in industry. (Oral answers, July 6.)

NEW WORLD

Pernicious Relevance

from our Washington Staff

Does the United States need a national science policy? That is the subject of hearings which have just started before Mr E. Q. Daddario's Congressional subcommittee on science, research and development. While still juggling with technological assessment (*Nature*, **226**, 894 and 998; 1970), Mr Daddario has skilfully thrown another ball into the air alongside. His latest enterprise has been to table a resolution before the House of Representatives which states that a national science policy is required to provide a basis for the coordination of scientific and related activities. If Congress passes the resolution, all Federal agencies will have one year in which to suggest how such a policy should be implemented.

No longer is the pursuit of knowledge for its own sake a respectable activity; rather must all projects be examined in the cold light of the immediate needs of society—basic research should be reduced from an end to a means. Although such is doubtless not the conclusion which Mr Daddario expects to emerge from the hearings, advice of this nature is rampant. And in introducing the hearings, Mr Daddario observed that, whether or not a new rationale is needed for science, this is certainly an appropriate time to question how the government should seek to support and direct scientific research.

"Throughout the world, but especially in the United States, the attitude toward science and technology that is the most vociferous is no longer one of awe or worship, but of fear and hostility. Science and technology . . . are the gods that failed." This was the view of Dr D. K. Price, dean of the Kennedy School of Government at Harvard University. He agreed with Mr Daddario's assessment that the relationship between science and government has been stable since 1945, but is now faced with radical alterations. In the present climate of opinion, said Dr Price, the ways in which science has hitherto been supported are no longer tenable.

How does government organize its support of science at present? Very largely, basic scientific research has been supported by using funds which were appropriated for rather more practical national objectives, such as military power, space exploration, or medical care. This support has come from a large number of government agencies, including the Department of Defense, the National Aeronautics and Space Administration, the Atomic Energy Commission, the National Science Foundation, and the National Institutes of Health. Each agency has supported whatever

research it saw fit to; there have been no restrictive policies detailing which agencies should support which topics of research.

But the writing is now on the wall; all the witnesses to testify before the subcommittee agreed that the present system has outlived its usefulness. Dr Price, however, observed that it did have good qualities that are likely to be lost in the transition to a new system—largely the generous provision of funds and the degree of freedom allowed to those spending them. But Dr A. H. Dupree, professor of science history at Brown University, did not even pay homage to the successes of the old system; he urged that a new science policy is badly needed and its introduction cannot be postponed. Following the modern trend, he argued that the relation of the DOD to basic research must be reconsidered; science must pay more attention to environmental problems; the space programme must find a role for itself with predominantly scientific objectives; and the social sciences must receive greater emphasis.

The first real live scientist to appear before the subcommittee was Dr L. A. DuBridge, director of the President's Office of Science and Technology. He said that developing a federal policy for science and technology is no easy task; everyone agrees that the progress of science and technology is important to the country, but no one has established principles which would determine just how the government should organize its support. Dr DuBridge distinguished between science and technology and pointed out that a single federal policy cannot cover both of them. Technology he defined as those research and developmental efforts which are aimed at specified practical goals and are supported to the degree that such goals are thought to be important to the federal government. Science, on the other hand, must be regarded as an activity which is supported not because there is a specific practical end in view, but because it is deemed desirable to expand the bounds of human knowledge.

From this foundation, he launched an attack on the pernicious doctrine of relevance—that scientific research should be orientated toward the needs of society. Because it is impossible to foresee which area of scientific research will yield what kind of knowledge or what kinds of application that knowledge will have, he said, any federal policy relating to the federal support of knowledge-directed science must be based essentially on the faith that knowledge as a whole is useful and beneficial to mankind. This encouraging rebuttal of present attitudes was in contrast to the

rather more pragmatic advice of Dr Price, who had previously argued that the effective justification for academic freedom and university independence is not that scholars should have special privileges; rather the types of control that raise standards of performance in industrial or administrative work would degrade standards in scholarship.

It was wrong, Dr DuBridge continued, to exclude agencies such as the DOD, AEC and NASA from supporting basic research, if only because it is impossible to define their future needs. He pointed out that the Mansfield amendment approved by Congress has stopped the DOD from supporting other than directly relevant research, and some of the university projects most valuable to the country (about \$8 million worth) have been cut out because the DOD was unable to prove their relevance to defence.

Man has had value for money so far as investment in basic research goes. According to Dr DuBridge, the total amount that has been invested in knowledge-directed scientific research throughout all history probably totals not more than about \$27 billion—and this is the basis for a trillion dollar economy in the USA. A policy for science as contrasted to technology, he concluded, must be one which simply recognizes the fact that the nation must have a strong scientific basis which must be maintained and allowed to grow with the GNP.

PUBLIC HEALTH

New York City's Health Corporation

from our New York Correspondent

THE largest non-federal hospital system in the United States was recently turned over to a quasi-public corporation. New York City has yielded up the 18 hospitals that have comprised the City's Department of Hospitals to the Health and Hospitals Corporation, in an attempt to cut through the bureaucratic red tape that has plagued the department in recent years and to increase the responsiveness of the hospitals to the needs of the communities they serve.

To meet the health needs of nearly half of the city's population, the corporation will have a budget of \$617 million in the coming year, of which \$175 million is guaranteed by the city, the rest coming from federal medicare and medicaid funds, from private health insurance payments and from various state and federal grants. The corporation will also oversee more than one billion dollars in construction that has already been approved or is under way.

Dr Joseph T. English, the head of the new corporation, has described it as "probably the most significant new venture in the development of quality health care in a large complex metropolitan area that we're going to see in this country in some time". In spite of this enthusiasm, there has been much controversy in the city over the transfer of power from a city agency to a public corporation. Critics of the new corporation claim that the city is simply abdicating responsibility for the health needs of the city, while proponents believe that an independent corporation is the only way in which health care can be made efficient and responsive to local needs.

Herman Badillo, the former Bronx Borough president, has agreed to serve on the corporation's board of directors but continues to be an outspoken critic.

In a recent speech, he stated that, "by removing the hospitals from direct government control, we're making them even more remote from the people. The mayor can say, 'It's not my responsibility.'". Another critic of the corporation is City Council president Sanford D. Garelik, the only member of the Board of Estimates to vote against the agreement between the city and the corporation.

"I voted a strong protest against the philosophy of government that the corporation represents," Mr Garelik has said. "All it does is take the hospital system farther from the people."

In reply to these criticisms, supporters of the corporation point out that reforms have been attempted in the past with little effect because of the structure of the city charter and because the hospital agency has had to deal with the central city agencies on all budget, personnel, and purchasing requests. "This has led to a tremendous middleman bureaucracy, making it impossible to have good, sound local decision-making," said Robert A. Derzon, the present deputy commissioner of hospitals. Mr Derzon, who is leaving at the end of July for a job in San Francisco, added that, "Under the old agency structure, local elected officials couldn't implement local policy even if they wanted to. We are more interested in decentralizing, not centralizing; we need strong local management and to get this we must be able to give each hospital autonomy to run its own affairs."

The present situation has grown out of a historical development unique in the United States. While most American cities have only one or two public hospitals, New York City since the turn of the century has placed much more emphasis on social services. The great influx of poor immigrants into the city led to a rapidly expanded public health care system. Public hospitals thrived during the 1920s and especially during the depression, when jobs were scarce and doctors were pleased to train in public hospitals. During the Second World War, the system slid downhill as many doctors went into the army. Afterwards the gap increased because few doctors had been trained. With limited staffs, the public hospitals were no longer able to attract specialists; it was no longer prestigious to be affiliated with the city's hospitals and they became dependent upon a large influx of foreign physicians. In 1959, more stringent accreditation regulations made it even more difficult for foreign doctors to practise in New York.

At the same time, the city itself was changing. The migration of the middle and upper middle class families for the suburbs meant fewer doctors and a declining tax base. One attempt at a solution was the affiliation programme instituted in 1960, when many of the public hospitals became teaching hospitals in association with the medical schools in the city, and when the public and private sectors of health care were brought closer together. But however finances were bolstered, the hospitals themselves did not change.

When the federal medicare and medicaid programmes came into effect in 1966, nobody was ready. There were now enough doctors, but few nurses or other paramedical personnel and few good facilities. In a city where now nearly half of the population depends on the city to provide some or all of its medical care and where four fifths of the aged and one third of the children rely solely on the public hospitals, widespread public criticism of the hospital agency led to a

number of official investigations. These brought to light much of the inefficiency and red tape and the general inability of the agency to respond rapidly to community needs. All of the commissions recommended an immediate reorganization of the municipal hospital system. The Health and Hospitals Corporation is the result.

The 18 municipal hospitals have 16,000 beds, an annual average of more than 4.7 million in-patient days and 2.9 million out-patient visits. The corporation will be one of the major employers in New York City and, with health care one of the fastest growing industries in the country, its role in the city should expand rapidly over the next few years.

To keep pace with this growth, the corporation is empowered to issue bonds, buy equipment and to bypass civil service regulations in hiring personnel. While capital investment will be tightly controlled by the city budget, the corporation will not be required to go through the Department of Public Works for construction and repairs as is presently the case. Nor will it have to use the central purchasing agency unless it wishes. In the past it has taken an average of 88 days to complete purchase requisitions and usually nine months for a hospital to hire new personnel. The corporation will delegate much greater authority to individual hospital administrators, allowing each to hire his own personnel and to spend a certain amount of money without consulting the corporation.

Advocates of the corporation feel that the elaborate system of checks and balances built into the corporation, combined with an influential and knowledgeable board of directors chosen by the city and serving five-year staggered terms, will insure that the corporation continues to be responsive and responsible to the city's health care needs. Mr Derzon claims that the board is anxious to be innovative in preventive medicine by establishing closer ties between the clinics and the hospitals, and that it hopes significantly to involve consumers. "Under the law, consumer advisory boards representative of the community are to be set up at every hospital." He recognizes, however, that the growth and development of hospitals will become political questions.

In spite of the controversy about the corporation, the prime consideration facing the corporation is whether or not it can provide the services the city needs now and in the future. However well it has been organized, its success or failure will depend on the calibre of the administrators who are running it. This is a familiar and daunting problem in the city. Many of the top members of the present hospital department have left or are leaving. Dr English will have a difficult time replacing them.

EARTHQUAKES

Death Toll in Peru

from our Geomagnetism Correspondent

THE recent earthquake in Peru (*Nature*, 226, 1087; 1970) will no doubt give geologists and geophysicists added incentive—and data—in their attempts to predict and modify such events. Only time will tell whether these efforts will succeed, but meanwhile other things can be done to reduce injuries and loss of life. The number of people killed and injured in an

earthquake depends on nature's variables—the magnitude and position of the earthquake—but it also depends on man's follies and limitations. In the Peru earthquake, as it turns out, about two thirds of the estimated 50,000 deaths were caused by the collapse of structures—mainly adobe dwellings constructed of sun-dried clay and straw materials.

Over the coastal area and in the Huaylas Canyon severe damage and collapse were restricted almost entirely to adobe constructions on unstable alluvial soil. In the hardest hit Huaylas Canyon, where 35,000 people died, about 90 per cent of the buildings are of this type. Concrete and steel structures, on the other hand, survived much better. In Chimbote, a city of 100,000 nearer the coast and the earthquake epicentre where the proportion of adobe dwellings is smaller than in the mountain villages, the proportion of deaths relative to the population at risk was much smaller (2,600).

At present there is certainly no non-collapsible wonder building which will completely eliminate earthquake deaths, and there may never be. Nevertheless the moral to be derived from the Peruvian disaster is quite clear. Construction engineers must find ways of strengthening the typical adobe construction; and new regulations should be made limiting new adobe dwellings to one storey and insisting upon light roofing materials. Ideally, of course, adobe dwellings should be eliminated altogether, but at present this is economically out of the question in Peru, Mrs Richard Nixon's visit notwithstanding.

TOLBUTAMIDE

Hazards of Leaks

THE recent furore over the use of tolbutamide to relieve diabetes has revived criticisms—never very far dormant—that the Food and Drug Administration does not take sufficient precautions to prevent the press from first unveiling to the public reports of the results of clinical trials of drug efficacy. Patients have been unnecessarily alarmed, it is alleged, by reading about the possible harmful side effects of drugs even before their doctors have been informed.

Tolbutamide is a sulphonurea drug which is given orally to treat patients with maturity onset diabetes. It was approved for use in 1957; as a result of a general review of drug efficacy, the FDA revised the labelling of the drug in 1968 to indicate that its principal value was for patients whose condition could not be controlled by diet alone. The use of other sulphonurea drugs was explicitly limited to such cases.

Together with other sulphonurea drugs, tolbutamide was reviewed for its efficacy and for its effect on diabetes complications in a clinical programme which started in 1960. The trials compared the effects of various regimes of treatment on patients in whom maturity onset diabetes had recently been diagnosed, but who were not insulin dependent and were expected to live for at least five years after their entry into the study. All patients were placed on a diabetic diet; one group was given a placebo as well; one a fixed amount of tolbutamide, and the remaining two were treated with insulin.

Two conclusions emerged from the report of the trials, received by the FDA this year. Tolbutamide

seemed to be no more effective than diet alone, and there was a statistically significant excess of cardiovascular mortality in the patients treated with tolbutamide compared with those in the other groups. The FDA does not regard these conclusions as final, however, because the trials tested the effect of a fixed amount of tolbutamide on only limited types of diabetic patient.

The details of the report have not yet been made public. Unfortunately, however, the report was disclosed to the press and the finding that mortality is fifty per cent higher after eight years of treatment with tolbutamide received the full glare of publicity. The FDA then promptly issued a press release which said that oral anti-diabetic drugs should be prescribed only for those patients who cannot be controlled by diet alone; the dose should be adjusted to the needs of the individual patient; and patients taking the drug should continue to do so unless advised otherwise by their doctor. This information was simultaneously telegraphed to doctors. The FDA is now writing in further detail to doctors, and the labelling of the drug will be changed.

What action does the FDA propose to take to prevent future such reports from seeing the light of day before doctors have been informed? Although there is concern that patients should have first heard of the hazards of tolbutamide through the press, and the problem of how to first inform doctors is being studied, no answers have been found yet. Dr C. C. Edwards, Commissioner of the FDA, said recently that "unfortunately, there is as yet no practical way of informing the physician in each case before the information reaches the patient via the lay press".

POWER

Rads or Brownouts

THERE is a critical shortage of electric power in the US, warned Dr L. A. DuBridge, the President's science adviser, in a recent address to the American Nuclear Society in Los Angeles. He said that there is "the possibility of a major failure which could produce enforced blackouts of disastrous proportions". Recent years have seen both extensive brownouts—when consumers are asked to use less electricity (people were asked to turn off their air conditioners on the hottest day of the summer last year in Washington DC) and the voltage may be reduced—and blackouts, the most spectacular of which plunged most of the north-east of the USA into darkness in 1965.

The nation's insatiable appetite for electric power, both at the consumer and at the industrial level, demands continual increases in the provision of electric

power. Table 1 shows that increases in electric power capacity are expected to run well ahead of increases in population during this century.

With increasing concern about the rapid depletion of fossil fuel resources, nuclear power has been proposed as the best answer (albeit impermanent in that nuclear resources are themselves finite). As Table 1 shows, nuclear power is expected to provide an increasing proportion of electric power.

But hassles about the effect of nuclear reactors on the environment are holding up the nuclear power plant building programme. Although nuclear reactors have certain obvious advantages over fossil fuel plants—they are free from discharges of noxious sulphur dioxide and nitrous oxide fumes and smoke—they suffer from compensating disadvantages. Because nuclear power plants are less thermally efficient than the best of the coal or oil fired plants, they discharge up to about one third more waste heat into the environment. This disadvantage may be overcome by developing new types of reactor which will operate with greater thermal efficiencies, but in the meantime there is some concern that the thermal impact of nuclear power plants may cause climatic changes.

A much more vaunted hazard of nuclear power is the risk of increasing the level of radioactivity in the environment. Although critics of the nuclear power programme have recently received publicity for their charges that the extra exposures to irradiation which could be permitted by the regulations imposed by the Atomic Energy Commission could result in a 10 per cent increase in the number of cases of cancer or leukaemia in the US, the AEC maintains that such estimates are grossly exaggerated. Dr T. J. Thompson, Commissioner of the AEC, recently stated that "the hazard from reactors to the population as a whole is at an extremely low level and is being badly distorted in the present overcharged climate of emotions". More specifically, he remarked that the increased exposure to radiation near the edge of a nuclear reactor site is equivalent to that gained by living on top of a 400 foot hill instead of at the bottom. This must be a very small amount compared with the natural background of radiation. Indeed, Dr Thompson said, there is probably statistically less than one extra case of cancer or leukaemia as a result of nuclear reactors. By comparison, the environmental pollution from coal fumes and smog causes very much more damage.

Notwithstanding such reassurance, "conservationist" opposition to the construction of nuclear power plants is slowing the building programme. This is not, however, the cause of the present brownouts and blackouts, which result from underestimates of power requirements which were made some five years or more ago, when many of the present power plants were designed and built. The present concern over environmental pollution is likely to result in insufficient provision of power facilities in 1975 and after. The AEC's concern over the slowing of the nuclear power plant building programme is reflected in continual tightening of the conditions for design and operation of nuclear reactors. One notable attempt to reassure public opinion about the safety of nuclear reactors is newspaper advertisements which point out that President Nixon's Western White House at San Clemente, California, is within striking distance of a nuclear reactor. If it is safe for the President, imply the advertisements, it is safe for everyone else.

Table 1. ELECTRIC POWER CAPACITY OF THE US

Year	1950	1969	1980 est.	2000 est.
Population	152	204	235	320 million
Total power capacity	85	313	668	1,352 million kW
Nuclear power capacity	0	4.3	150	941 million kW
Nuclear proportion	0	1	22	69 per cent

NEWS AND VIEWS

Mapping Human Genes

UNTIL the linkage groups and chromosomal locations of human genes have been determined human genetic engineering will remain little more than a pipe dream. That is not, of course, to say that ignorance of human somatic cell genetics is all that stands in the way of genetic engineering. Even if linkage groups assignable to every human chromosome were known today genetic engineering would not immediately become a practical proposition, but without such information any attempt to change purposively the genome of a human cell has little chance of success. It is not surprising, therefore, that the genetic analysis of human somatic cells is currently attracting a great deal of attention and that the experiments reported by Bodmer and his colleagues, on page 248, and Ruddle, Chapman, Chen and Klebe, on page 251, are so welcome.

These experiments strongly suggest that the structural genes for two human enzymes, peptidase B and the B subunit of lactate dehydrogenase, are linked and located on an autosomal chromosome. Moreover, both groups agree that the structural gene for the A subunit of lactate dehydrogenase is not linked with that specifying the B subunit, and apparently Bootsma and his colleagues in the Netherlands have reached this conclusion independently using a different experimental system. Although linkage between human genes on the sex chromosomes has been reported this seems to be the first example of a human autosomal linkage group, and the work is yet another testimony to the power of Watkins and Harris's technique for inducing the fusion of somatic cells by treating them with inactivated Sendai virus.

Both groups approached the problem of establishing gene linkage in the same way. They used Sendai virus to fuse human white blood cells with mouse cells of the stable cell lines 3T3 or RAG. The resultant human mouse hybrid cells preferentially shed human chromosomes as they are cultured. This, as yet unexplainable, phenomenon can be exploited to establish linkage between human genes simply by assaying a series of hybrid cell lines for human gene products, in this case enzymes, which can readily be detected by gel electrophoresis of cell extracts. Leaving aside any complications arising from regulator genes, chromosomal translocations and selection pressures for the retention of particular human chromosomes, if two human genes are linked and are on the same chromosome the enzymes they specify will only be present in hybrid cells retaining that chromosome. Once the chromosome is lost both enzymes should be lost simultaneously. So by correlating the enzyme activities of a series of hybrid lines it should be possible to establish gene/gene linkage, and by examining the karyotypes of the hybrids and analysing the number and type of human chromosomes they retain it should be possible to

decide which chromosome carries the linked genes.

It scarcely needs saying that experiments of this sort are extremely tedious in practice and fraught with pitfalls. Any translocation of chromosomal material can result in an apparent but spurious linkage. The instability of the karyotypes of human mouse hybrids and the occasional appearance in a hybrid line of a chromosome unlike those of their parent cell can cloud the issue. And if the expression of the structural genes being analysed is controlled by regulatory genes, which are unlinked, the interpretation of patterns of enzyme activity in hybrids can become hopelessly complex. Furthermore, if the particular murine and human enzymes have the same electrophoretic mobilities, as do murine and human lactate dehydrogenase B subunits, distinguishing them in cell extracts poses considerable problems.

Aware of all these snags both Bodmer and his colleagues and Ruddle *et al.* have analysed enough hybrid cell lines, clones and subclones to conclude that human lactate dehydrogenase B and peptidase B genes are linked. There is a positive correlation between the occurrence of the two enzymes; hybrid cells either have both or neither. And the combined data make it highly unlikely that the two enzymes are on different chromosomes which are always lost concomitantly, or that the structural gene for one enzyme is linked to a regulatory gene for the other. Moreover, according to Ruddle *et al.* analysis of the inheritance of the mutant form of lactate dehydrogenase B, in the family of the mother and daughter whose leucocytes they used to make hybrids, indicates that the two genes are located on an autosome. Neither group found any evidence of linkage between about a dozen other enzyme activities which they assayed in the hybrid cell extracts. Having identified this one gene linkage the next, and far more tedious, step is to identify the autosome which carries the two genes.

This will involve searching for correlations between the enzyme phenotypes and the complements of human chromosomes in a set of hybrid cell lines. Ruddle and his colleagues have made a start, identifying the human chromosomes in their hybrids by their morphology and their failure to hybridize mouse satellite DNA or its complementary RNA. Most of their clones apparently contain between ten and sixteen human chromosomes with representatives of each class. They have not yet identified the autosome which carries the lactate dehydrogenase B and peptidase B genes, but they have managed to confirm that the unlinked lactate dehydrogenase A gene is on a C group chromosome, possibly the X chromosome.

What of the future? These experiments establish that hybrid cells can be used to identify autosomal

linkage groups. As the number of antigens, enzymes and other genetic markers that can be readily assayed increases, the technique is bound to become more popular, and other linkage groups will soon be recognized. After that the problem will be to refine methods for the analysis of linkage within a particular chromosome. For example, it may be possible to do this by

analysing the phenotypes of cells containing chromosomes which have suffered deletion mutations of varying severity. As for medical exploitations, a dictionary of human linkage groups could immediately prove useful, in foetal medicine, for the early detection of genetic metabolic defects, or for the antigenic pre-selection of sperm before fertilization.

Chip Off the Old Block

No international committee likes to die a natural death, so the phoenix-like emergence of an International Geodynamics Commission to take over the running when the Upper Mantle Project comes to an end is hardly a surprise. By all accounts Professor Coulomb of Paris, who is bowing out of geopolitics after distinguished service, was concerned that a strong body should continue to exist, and an *ad hoc* committee has been at work in the past year trying to pinpoint the growth areas which needed emphasizing. As a result of this, a report was issued last July recommending a strong interdisciplinary approach to the problems of earth sciences in the '70s. The emphasis of this report is very firmly on the new tectonics approach and on the significance of lateral heterogeneity in all properties of the Earth in the outer 700 km. It is satisfactory that the report was constructed by relatively young earth scientists who have contributed much to our present understanding of the Earth, and the international example of letting the youngsters decide the programme is one that many national committees would do well to emulate.

The Commission has recently had its first meeting to produce an agreed statement and four needs were emphasized in these meetings.

(1) An increased understanding of the forces and processes between lithospheric blocks or plates.

(2) Studies aimed at understanding the driving forces on these blocks, involving *inter alia* laboratory studies at high pressures and temperatures.

(3) Some new ideas on the as yet little understood vertical movements within blocks.

(4) Palaeogeophysical studies to determine whether present day processes were equally valid in past geological time.

Partly from an obvious desire to relate global geophysics to human needs, the Commission appears to have placed hope in economic advantages from deep drilling programmes comparable with the present JOIDES project. A recent discovery of copper in a JOIDES hole may help their case.

The Commission's deliberations are notable both for what was included and what was omitted. The very strong emphasis on a block or plate approach to the earth sciences is most important. Some people who should know better seem woefully ignorant of the enormous implications of the revolution of the last three years. The Commission has clearly laid down

its belief in these new approaches and also in problem orientation rather than science for science's sake. Equally it has been careful to avoid giving any pats on the back to specific projects which might lead to its being used as a lever to extort financial support. Notably absent is any great enthusiasm for planetary exploitation, for local studies of "unusual regions" and for geotraverses (whether seismic, magnetic or gravity) —vastly expensive and largely useless operations that some countries have in the past committed themselves to.

So there is no recipe to national committees on what to support and what not to support, but a fairly clear indication of the direction in which the experts feel things should go. What exactly the Commission will succeed in doing remains to be seen. It has little power except persuasion and it is undoubtedly going to alienate many by being so forward-looking. The earth sciences are moving so fast that there are bound to be many who fall by the wayside, but on the other hand the quality of new recruits to the subject is encouraging. At first sight the Commission seems to be defining goals which are accessible to very few, but undoubtedly it will try to encourage all workers in the field to see national capabilities in a global programme. Whether Britain acts to implement financially work which is in accord with the aims of the Commission remains to be seen. Its record of official support for the Upper Mantle Project was not very inspiring despite the fine reports which were periodically distributed showing everyone apparently working on the Upper Mantle. There is clearly no reason why Britain should force earth scientists to follow the precepts of the Commission. On the other hand one hopes that there will be at least an awareness of the need to give extra help to those who take its recommendations seriously.

POLYNUCLEOTIDES

Looking at Coils

from our Molecular Biology Correspondent

It is clearly possible to leap into the deep end of molecular biology and survive, with no more knowledge about the physical properties of nucleic acids than what pairs with what. But to uncover the rules that govern the structures and interactions of nucleic acids it is necessary to study the properties of the ordered

and disordered forms individually and in depth. In spite of much work and some argument on the nature of the stacked state of unpaired polynucleotides, little thought has been given to the properties of the unstructured chain. This has now been rectified in a monumental study by Inners and Felsenfeld (*J. Mol. Biol.*, **50**, 373; 1970) on polyribouridylic acid. This polymer serves as an archetype for the disordered state, for in aqueous solutions its optical properties are consistent with the absence of any appreciable interaction between the bases.

As in the earlier work from the same laboratory on poly A, it proved possible by selection of ionic strength and temperature to find conditions of ideality, where the combined effects of polymer-polymer and polymer-solvent interactions effectively vanish. A precipitation method was devised for fractionating the poly U into cuts of narrow molecular weight range. The dependence of sedimentation coefficient and intrinsic viscosity on chain length obeyed the law required for a random coil. With changing temperature these parameters and also the radius of gyration, determined from light-scattering, which measures the flexibility of the coil, showed only a small and gradual change, by marked contrast with poly A, which displays large changes in physical properties, as the stacking interactions diminish. A quantitative expression that defines the flexibility of the coil can be derived by relating the radius of gyration to the number of monomer units in the chain, and the length of each. This expression turns out to be independent, as it should be, of the molecular weight, and its magnitude betokens a stiff chain, quite different from polyphosphoric acid, for example. It is equally, however, very different from stacked poly A, but essentially identical with unstacked (melted) poly A, so that the dimensions in solution of a disordered polynucleotide appear to be unrelated to the nature of the base. It follows from the value of the coil parameter that there must be extensive restrictions on the permitted rotational angles. Conversely, if one can guess at the values of the six angles of rotation that define the chain geometry, one can calculate the coil dimensions. Now crystallographers have noted that all the angles fall into narrow ranges for the many nucleotides and base-paired polynucleotides of known structure. Inners and Felsenfeld have shown that if these values apply also to poly U in solution, they lead to calculated coil dimensions that are entirely compatible with the experimental values. Not only this, but if the same computation is applied to poly A with introduction of stacking at random along the chain, the effect on the radius of gyration is again very like that actually observed. It remains only to determine why the restrictions on the freedom of the chain are so stringent in solution; one of the more likely contributing factors is that even at high salt concentration the repulsion between phosphates is sufficient to cause the distance between them to be maximized.

It may be noted that when the temperature falls to 10° C or below, an ordered form of poly U makes its appearance in a cooperative manner. Thrierr and Leng showed by light scattering, and Millar and Mackenzie (*Biochim. Biophys. Acta*, **204**, 82; 1970) now confirm by sedimentation equilibrium, that this transition is accompanied by no change in molecular weight, and must therefore be considered to involve the formation of hairpins folded back on themselves, or possibly more complex branched forms, such as are

formed in poly dAT at intermediate temperatures. In this connexion it is of interest also that a kinetic study has appeared (Yeh, *J. Chem. Phys.*, **52**, 6218; 1970), which depends on an interesting new technique that has been glittering brightly on the horizon. Diffusion coefficients can be determined from the wavelength distribution of scattered light, when a laser is used to provide a coherent incident beam: the doppler broadening of the scattered light then depends on the velocity of motion of the solute molecules. When, as here, two species of different hydrodynamic properties are in equilibrium, the method can in principle—and, it now appears, in practice, though various approximations remain to be properly evaluated—be used to extract the rates of interconversion from the line shapes, in a range extending to 10^7 s^{-1} . This could well become an important method for studying the kinetics of macromolecular processes.

TUMOUR VIROLOGY

Rapid Transformation

from our Cell Biology Correspondent

Baltimore and Temin's discovery of an RNA dependent DNA polymerase associated with the virions of tumour viruses (*Nature*, **226**, 1209; 1970) has, predictably, caused prompt reassessments of the research programmes of numerous laboratories. And by all accounts similar enzymes have been found in numerous RNA tumour viruses by virtually every group that has looked for them. Characterization of these enzymes and their DNA product is likely to remain a chief preoccupation for many months to come.

One of the more interesting questions to be answered is what is the fate of the DNA made by the enzyme? Is it integrated into the nuclear DNA of the host cell as Temin predicts? Hybridization experiments reported by Baluda and Nayak (*Proc. US Nat. Acad. Sci.*, **66**, 329; 1970) suggest that this will prove to be the case. They have measured the extent of hybridization between 71S RNA of avian myeloblastosis virus and DNA of leukaemic chick myeloblasts and normal chick embryo cells. In all, 1.7 times more viral RNA hybridizes to leukaemic cell DNA than to normal cell DNA and this difference is not simply the result of a differential but non-specific capacity of the two DNAs to bind RNA. Moreover, competition with a sixteen-fold excess of cold viral RNA reduces the binding of hot viral RNA to leukaemic cell DNA to the level obtained when normal cell DNA is used. Melting curves of the hybrids of the viral RNA and leukaemic and normal cell DNA show the respective values of T_m to be 92° and 87° C. Clearly, apparently normal chick cells contain sequences of at least 100 nucleotides complementary to the myeloblastosis viral RNA. Baluda and Nayak believe that this homology may indicate that the normal cells are latently infected with a tumour virus. Taken together, their results, although not completely conclusive, suggest that the DNA made from tumour virus RNA templates is integrated into the host cell DNA.

On page 245 of this issue of *Nature*, Hausen and Schulte-Holthausen report broadly similar hybridization experiments which reveal small amounts of EB virus DNA in a "virus-free" line of Burkitt tumour cells. This work, together with experiments of others which show that EB virus can transform cells in culture,

strengthens the suggestion that EB virus may be the causative agent of Burkitt's lymphoma.

Watson, Ralph, Sarkar and Cohn (*Proc. US Nat. Acad. Sci.*, **66**, 344; 1970) have reported experiments which raise the possibility that a leukaemia type virus is involved in the aetiology of mouse myeloma. They have found a positive correlation between the capacity of mouse myeloma cells in culture to synthesize immunoglobulins and to produce a murine leukaemia type virus. Using various tests, Watson *et al.* identified the virus-like particles seen in the myelomas and in their culture media as a virus closely related but not identical to known murine leukaemia viruses. The myeloma cells which produce virus carry the Gross leukaemia type G antigen and the viruses themselves have leukaemia group specific antigens. Moreover, Watson *et al.* have found that a variant line of myeloma cells, isolated by Schubert and Cohn in 1968, which fails to synthesize immunoglobulins also fails to produce virus. And some variant cells selected for lack of leukaemia antigens also failed to synthesize detectable amounts of immunoglobulin proteins.

DISEASE TRANSMISSION

Viruses on the Wind

from our Microbiology Correspondent

DURING the past few years, evidence has been accumulating to implicate climatic conditions as a major factor in the dissemination of foot and mouth disease. Last year (*Nature*, **223**, 712; 1969), Smith and Hugh-Jones reported that wind could be of primary importance, and now, two years after the last calamitous outbreaks in England and Wales, Hugh-Jones and Wright have published a study of the 1967-8 epidemic in relation to the then prevailing weather (*J. Hygiene*, **68**, 253; 1970). Although numerous agencies have been suggested as carriers of the virus—animals, carcasses, milk, bones, birds, rats, hay, vehicles and humans included—the cause of only 5 per cent of the outbreaks in 1967-8 was established conclusively. How then did most of the infections—more than 2,000—occur? Hugh-Jones and Wright's analyses show that wind and subsequent precipitation were strong contenders for the role of chief disseminating agents.

The first identified outbreak was on a farm at Nant Mawr, Shropshire, in October 1967. The pattern of the spread of the disease from this centre conformed to that predictable for windborne spread from a point source. The mean bearing of outbreaks in the invasion sector was 039°, while the concurrent mean surface and 2,000 foot wind directions were 034° and 068° respectively. Moreover, a calculation of the axis of a plume of windborne material in these conditions gave a value of 041°. Thus, the initial spread in the epidemic of 1967-8 was aerial and relatively close to the ground.

An investigation of a sub-epidemic near Worcester proved particularly interesting because of its isolated situation. Foot and mouth disease was introduced into this area in skim milk pig feed, but subsequent spread in the locality was by other means. Indeed, the subsequent pattern of outbreaks accorded closely with the weather conditions. Thus, there was little if any spread during a subsequent dry, anticyclonic period with little wind, although there were adequate numbers of susceptible stock on nearby farms. With the return of

rain, however, there were fresh incidences of the disease. As well as transmission of the virus for short distances by wind, cases of windborne infection for 60 to 110 km were detected. The data collected from the 1967-8 epidemic also point to an association between wind speed and rate of spread of the disease. In mid-November, for example, a sharp decrease in the rate of spread coincided with the onset of dry weather, whereas maximal rates of spread later in the winter correlated with periods of snow bearing winds.

If foot and mouth disease is transmitted by wind, several assumptions relating to the release of the virus into the air, its transportation and eventual deposition must be made. The virus can be emitted from infected animals in several ways, including sneezing, and probably appears in droplet nuclei in the air. The size of the droplets largely determines the extent of spread; strong winds which dehydrate and fragment large droplets lead to greater spread. One case history investigated in detail by Hugh-Jones and Wright argues forcibly for an aerosol transmission of foot and mouth disease. In concluding that wind is responsible for spread they are rather pessimistic about the chances of finding an effective means of containing the disease. Accurate weather forecasting coupled with early diagnosis should aid farmers and epidemiologists and enable them to alert and concentrate on areas of probable infection. Immediate slaughter of all infected and contact animals remains the chief method of choice for containing the disease in Britain.

IMMUNOCHEMISTRY

Eye on Antibodies

from a Correspondent

IMMUNOCHEMISTS from ten laboratories cross matched almost seventy antibodies to the proteins of the vertebrate eye lens when an international working party on crystallin immunochemistry met in the MRC Epigenetics Research Group, Edinburgh University, from June 23 to July 6. Additional antibodies are expected from three more laboratories. The lens of the vertebrate eye is often used to study problems of embryonic induction, tissue specificity and metaplasia, regulation of protein synthesis and protein evolution. Lens proteins, or crystallins as they are called, are also studied in cataract and other human pathological conditions. Because the crystallins are non-enzymatic, immunochemical procedures are used in their recognition. If antibodies of unknown differences in specificity are used discrepancies in the literature are to be expected, yet it has become increasingly necessary to be able to make detailed rather than very general correlations between data from various laboratories. To achieve this, the antibodies were cross matched both qualitatively and quantitatively in standard conditions against a panel of antigens.

The test panel included antibodies to total crystallins of fifteen species including man, bovine, chick and amphibia and antibodies to restricted fractions from several of these species. The panel of test antigens included total crystallins of fourteen species to fourteen different preparations of human, bovine, and chick crystallins fractionated by chromatography or isoelectric focusing and ten highly purified bovine crystallin fractions, including crystallin subunits.

Four types of antibodies will be designated and reserved in a reference collection: (1) antibodies detecting the maximum number of antigenic constituents in a specified antigenic preparation, which may be used as a reference to compare antibodies from different laboratories with respect to the antigens recognized; (2) antibodies specific to a class of crystallins within a species; (3) antibodies which discriminate between members of a class of crystallins; and (4) antibodies which discriminate between antigenic determinants in highly purified preparations. The last two types include species cross-reactive antibodies.

The results of the cross matching will also be examined to determine the number of antigenic determinants detectable within a class of crystallins of a given species, and compare the antigenic composition of a range of species.

Plans were also made for exchanges of antibodies and purified antigenic preparations between biochemists and immunologists. This will make possible both the detection of minor impurities in protein preparations and the production of antibodies against specified constituents.

A full report of antibody specificities and standards and other findings will be published, together with a list of participants and acknowledgments to the organizations which financed the working party, the firms which helped with loans of apparatus and the biochemists who donated purified crystallin preparations. Pending the collation and publication of results any investigators who have anti-crystallin antisera which they would like to have cross matched against the present panel of reagents are invited to communicate with Mrs R. Clayton at the Institute of Animal Genetics, Edinburgh University.

CROPS

Rice Races Raised

WORLD records for the annual production of rice have been claimed by experts at the International Rice Research Institute in the Philippines. Dr S. K. De Datta writes: Three crops were harvested between January 1969 and January 1970 at the experimental farms of the institute, in Los Baños, and of the Central Mindanao State University. At Mindanao the highest total yield came from a transplanted indica line, IR593-3-17, which produced 23,553 kg/hectare in 315 days (Table 1). As far as we know this is the highest authenticated annual production recorded from a single variety or line. The highest yield previously reported for three crops of transplanted rice was obtained at Ivoloina Experiment Station in Madagascar, when a japonica variety, 'Chianan 8', produced 20,430 kg/hectare in 335 days (J. Velley, *L'Agronomie Tropicale*, No. 8, 669; 1969).

At Mindanao IR20 and the well known dwarf variety IR8 also gave very high yields (Table 1). IR20, a variety newly released from the institute, produced 23,226 kg/hectare in three crops in 300 days; IR8 produced 22,826 kg/hectare in 316 days. When the total yield was computed by adding the three best yields the annual production was 24,279 kg/hectare; our previous record was 20,174 kg/hectare (*International Rice Research Institute Annual Report*, 1966). This is a reasonable calculation to make because many

Table 1. YIELDS OF THREE CROPS OF TRANSPLANTED RICE IN MINDANAO IN 1969-1970

Variety or line	Crop	Yield of grain (kg/hectare)
IR8	Jan. 16 to May 6	10,081
	May 21 to Sept. 3	6,133
	Sept. 11 to Dec. 21	6,612
		22,826
IR20	Jan. 16 to Apr. 25	9,392
	May 21 to Sept. 4	6,828
	Sept. 11 to Dec. 15	7,006
		23,226
IR593-3-17	Jan. 16 to May 4	10,274
	May 21 to Sept. 3	6,102
	Sept. 11 to Dec. 22	7,177
		23,553

Each crop received 60 kg/hectare each of P_2O_5 and K_2O . For each variety and line nitrogen was applied as 140 kg/hectare to the first of the three crops, 120 kg/hectare in the second and 80 kg/hectare to the third.

farmers who grow three crops in a year use three different varieties.

In our experiment at least 49 days were available to prepare the land for the three crops, an important consideration for the farmer. It is relatively easy to grow three crops with, say, 120 day maturity within 365 days. But this leaves only 5 days for the preparation of the land, which is not enough in real farming conditions. If, however, at least 10 days are available between each crop, three crops a year are within the reach of good farmers.

Table 2. YIELDS OF BROADCAST IR8 AT LOS BAÑOS DURING 1969-1970

Crop	Yield of grain (kg/hectare)
Jan. 8 to May 7	8,840
May 13 to Sept. 2	5,525
Sept. 11 to Jan. 2	6,718
	21,083

Nitrogen was applied as in Table 1.

At the institute's farm, IR8 gave the highest yield—21,083 kg/hectare in 365 days—after being grown from seed rather than from transplanted rice (Table 2). In spite of this success it is not likely that the use of broadcast seed will be adopted widely in Asia in the near future, for it will require a controlled water supply, which the monsoon season hardly provides, and very careful management if such high yields are to be repeated.

PLANT BREEDING

More Room for Growth

by our Botany Correspondent

THE gates of the Plant Breeding Institute in Cambridge were opened on July 9 to a bevy of inquisitive visitors who gathered for the opening of a much needed new block of laboratories. Called the Douglas Bell Building,

it is named in honour of Dr G. D. H. Bell, who has been director of the institute since 1948 and saw it set up on its present site in 1950. The prestige that plant breeding has attained during the history of the institute was underlined by the presence at last week's ceremony of the President of the Royal Society, Lord Blackett, who admitted that he had little contact with plant breeders during his youth in the Cavendish Laboratory.

While wandering through the laboratories and glass-houses, or riding by tractor around the extensive fields of experimental material, visitors could see clearly how the institute holds to its dual function of producing new varieties of arable and herbage crops, and promoting pure and applied research into many aspects of plant breeding. One of the teams that has moved into the new building is the cytogenetics group under Dr R. Riley, who has been appointed to take over the directorship of the institute when Dr Bell retires next year. Apart from the well known work on wheat, exploiting the genetic control of chromosome behaviour, there is a developing programme in barley cytogenetics. This is aimed at achieving the duplication of loci that will be useful in conferring disease resistance.

The biochemical genetics programme, which is to be concerned with phenomena of the nucleus and other organelles which are significant in crop genetics, has already produced some interesting results. Dr M. D. Bennet has found that for diploids the duration of meiosis is proportional to the amount of DNA in a cell. Although known already for mitosis this is the first time such a relationship has been identified in meiosis.

Bennet also thinks that he has found a possible reason for the instability of *Triticale*, the hybrid from wheat, *Triticum aestivum*, and rye, *Secale cereale*. Measuring the duration of meiosis, he obtained values of 24 hours for *Triticum*, 20.75 hours for *Triticale* (the fastest known plant in meiosis) and 51.2 hours for *Secale*. The discrepancy between the parents suggests that asynchrony of cell division is the cause of instability in the hybrid. This could be a very significant finding if it were the key to the problem of producing the highly desirable stable hybrids which would combine the useful features of *Triticum* and *Secale*.

One of the chief concerns of the plant breeders at the institute is the development of strains resistant to disease. One quite new programme—in progress for two years—is the search for sugar beet which is resistant to aphids. Dr H. J. B. Lowe has found that different clones of aphids prefer to live on different concentrations of sugar, and he suspects that resistance in this case depends partly on the concentration of sugar in the plants. Other substances such as amino-acids seem to be involved in a similar way.

With other crops progress has, of course, been more extensive, and visitors were shown a list of eleven varieties of various species developed at the institute and currently recommended by the National Institute of Agricultural Botany (NIAB). One of the most exciting of recent developments, the winter wheat Maris Beacon, has outstripped all rivals in yield during three years of trials at NIAB. Unfortunately yellow rust, developed last year, has delayed marketing of this variety. If it proves unduly susceptible to the disease it is hoped that a sister variety, Maris Nimrod, with equivalent yield, will prove resistant.

SLIME MOULDS

Further Cause for Attraction

from our Microbiology Correspondent

BONNER and his collaborators at Princeton report that they have distinguished a second chemotactic system in the slime mould *Dictyostelium discoideum* which has the distinctive property of stimulating vegetative amoebae. Describing their findings in the *Journal of Bacteriology* (102, 682; 1970) Bonner, Hall, Sachsenmaier and Walker report how an unknown chemotactic substance is produced by bacteria, that is if *Escherichia coli* can be taken as typical in this context. The conclusion of major significance is that this newly discovered agent and acrasin (cyclic-3',5' adenosine monophosphate) exert stage-specific responses on the developing amoebae.

Chemotaxis was tested by the 'Cellophane' square method devised some years ago in Bonner's laboratory. Vegetative amoebae are allowed to settle on small squares of washed 'Cellophane' which are then placed on agar containing the test substance. The test is read by recording the rate at which the amoebae move away from the 'Cellophane'. For acrasin, it is known that the movement of the amoebae is directed by a concentration gradient that is produced and maintained through the action of a specific phosphodiesterase (*Nature*, 223, 672; 1969).

Bonner *et al.* applied this test to cyclic-AMP and aqueous extracts of *E. coli* B/r. The mean rate of movement induced by a bacterial extract was significantly greater than that induced by 1.5×10^{-5} M cyclic-AMP. Furthermore, the chemotactic ratio, defined as the distance moved towards or away from a source over the total distance travelled, indicated that crude bacterial extracts had very strong orientation properties. Cyclic-AMP had a maximum chemotactic effect for concentrations of 10^{-5} to 10^{-8} M.

Bonner *et al.* argue that because the bacterial extracts produced a much greater degree of orientation, a chemotactic substance additional to cyclic-AMP was present. The new substance was demonstrated by another means. Being unable to diffuse through agar gels, the bacterial extracts freed of cyclic-AMP elicited no attraction when placed adjacent to small populations of vegetative amoebae. But such amoebae were attracted away from original populations when the dialysed extract was mixed into the agar. A concentration gradient of the new chemotactic substance is maintained, like cyclic-AMP, by secretion of an inactivating enzyme by the vegetative amoebae. Thus, dialysed bacterial extracts lost all activity within thirty minutes when incubated with the crude, extra-cellular amoebal enzyme.

The 'Cellophane' square test was applied to vegetative amoebae—those still feeding—and to sensitive amoebae on the point of aggregating, using cyclic-AMP and dialysed bacterial extract. With cyclic-AMP, the sensitive cells aggregated in large waves but vegetative cells responded poorly. The chemotactic peak of cyclic-AMP for sensitive cells was very sharp, with a maximum at 10^{-7} M. Similar experiments with the bacterial extract produced a very different reaction; the vegetative cells had a strong positive response while the aggregating cells did not leave the 'Cellophane' square. Thus there seems to be a switch in chemotactic response during the development of the amoebae.

Perhaps the newly detected substance is a prime means of food seeking (it is usually abundant during the vegetative stage when bacteria are present), whereas cyclic-AMP acts specifically in the aggregation process. The identity of the new substance will be keenly awaited. Its non-diffusibility does not especially worry Bonner and his colleagues; such a feature may have little significance in nature where soil and humus are the normal substrates.

TRANSFORM FAULTS

A Job for Coriolis

from our Geomagnetism Correspondent

IN spite of all that has been written about mid-oceanic ridges in general, and about transform faults in particular, no one seems to have given a really satisfactory explanation of why the faults are there. In his original description of transform faults, Tuzo Wilson supposed that the offsets were inherited from the shape of the break which first formed between the coasts of the adjacent continents—but really that just begs the question. And the question is quite important because, as Howell points out (*J. Geophys. Res.*, **75**, 2769; 1970), it is difficult to reconcile the offsets with a smoothly flowing convective system in the mantle. The sea floor spreads normally from each ridge section, but because each section lies at a small angle to the overall trend of the ridge the upwelling crest of any convective flow must be discontinuous.

Howell has come up with an ingenious explanation of how the bulk convective flow can be continuous and yet still be consistent with offsets. He suggests that it is all due to the Coriolis force, which causes the surface of the convection cell to drift sideways relative to the underlying flow. There is a well established precedent for such a phenomenon in the circulation of oceans and atmospheres. In the oceans, for example, a current at one level produces a flow at an adjoining level which is rotated clockwise in the northern hemisphere and anticlockwise in the southern hemisphere. In this case the effect can be so great that the net flow is normal to the surface driving force.

An obvious way to test Howell's hypothesis is to determine the sense of apparent rotation of the ridge sections relative to the overall trend. It turns out that more than two-thirds of the displacements are in the sense required by the Coriolis effect. Although this is a large enough difference to support Howell's idea, it suggests that Coriolis force is not the whole explanation. A second test derives from the variation of Coriolis force with latitude. Because the force is proportional to the sine of latitude, fault displacements should tend to be larger at high latitudes than near the equator. According to Howell, the total displacement along transform faults between 0° and 30° latitude is 61.4 arbitrary units, compared with 72.5 such units for faults between 30° and 60°. Unfortunately there are too few data above 60° to enable the comparison to be extended.

Hitherto, little attention has been given to the effect of the Coriolis force on mantle convection because for slow movements it is small. Runcorn, for example (*J. Geophys. Res.*, **69**, 4389; 1964), estimated that the Coriolis force was only 10^{-8} as large as the other forces involved. But the limits of error on this estimate are

certainly several orders of magnitude because neither the size of the convection cells nor the viscosity of the mantle material was known. Furthermore, there is no simple relationship between the magnitude of the forces and the amount of rotation they produce. Much depends on the coupling between the driving force and the mantle material and the thickness and viscosity of the layers through which the rotation is distributed. For these reasons it is impossible to give a realistic quantitative estimate of the effect of Coriolis force and thus definitely to rule it out. On the contrary, Howell shows experimentally that the Coriolis force is involved in some way. But because of its small size it is not surprising that it is not completely dominant.

AMORPHOUS SOLIDS

Shapely Currents in Carbon

by our Solid State Physics Correspondent

ELECTRICAL conduction in amorphous carbon seems to occur by a rich variety of processes, according to experiments by C. J. Adkins, S. M. Freake and E. M. Hamilton on thin films of carbon held in different conditions (*Phil. Mag.*, **22**, 183; 1970). At low applied fields, conduction along the films was found to be by a hopping process characterized by a special temperature variation with voltage, whereas at higher fields the mechanism was of the Poole-Frenkel type with a range of traps and a large effective dielectric constant. Conduction through the film was found to be appreciably poorer than along it, which was attributed to structural anisotropy in the films.

Within the past two or three years there has been a considerable upsurge of interest in the electrical properties of amorphous materials, and a recent review by a panel of the Science Research Council gave every indication that this interest will continue to flourish (*Nature*, **227**, 108; 1970). Carbon is a particularly suitable material to study in thin film form as the amorphous character of these films is strong. Electron microscope examinations suggest that the ordered structure is limited to 30 Å or less and that the crystallite size is typically no more than 10 Å.

Extremely large variations of resistance were found between different specimens, supposedly caused by variations in grain size and impurity content. The dependence of the resistance on temperature, however, at low applied fields and low temperatures was the same for each specimen, and followed the pattern predicted by Mott in which there is sufficient overlap of the localized states for tunnelling to occur beyond the nearest localized site.

At higher fields, the variation of current with applied field and temperature suggested to Adkins *et al.* the presence of Poole-Frenkel conduction. The parameter which denotes the trap depth turned out to be quite well defined above about 10 K, but decreased rapidly at lower temperatures. They point out that the drop in trap depth is not surprising as the extreme disorder implies a spectrum of depths of which only the most shallow would remain active at low temperatures.

They found that conduction through the film at low fields defied any simple explanation. The chief surprise was the flattening off of the resistance at 5 K as the temperature was lowered.

Relationships between Controllers of a System

by

SAMUEL EILON

Management Engineering Section,
Imperial College of Science and Technology,
London SW7

Many different arrangements of controllers can be designed to ensure the efficient functioning of a system. Whether the system is a complex piece of machinery or a committee in session, the principles are the same.

A SYSTEM with a control mechanism works satisfactorily as long as this mechanism does not deteriorate or break down. By "satisfactory" I mean that the behaviour of the system and its performance adhere to a set of standards; whether these are optimal or not is a different problem. Once the standards are defined and the control mechanism constructed, the system is expected to react whenever the standards are violated.

Control mechanisms, however, are susceptible to wear and failure, and when they cease to operate, performance may be substandard. For example, if an electric water heater is controlled by a thermostat which fails, the heater continues to heat the water well above the permissible temperature. A managerial control system is particularly prone to wear and tear: instructions may be ignored or circumvented and procedures misinterpreted or forgotten. Soon an intricate and polished communication and control system is no longer fully effective.

There are three possible methods of guarding against this. The first is to use several identical control mechanisms to operate in concert. "Identical" means here that the mechanisms are designed to operate and react to the same conditions and stimuli. Their internal structure and design need not be the same, but any variations in behaviour are attributed to chance variations.

The second method is to use non-identical controllers. These react to different sets of stimuli. The purpose of linking identical or non-identical control mechanisms is to provide an opportunity for the controllers to help each other in protecting the system from some specified undesirable breakdowns.

The third method is to check, continuously or occasionally, the performance of the control mechanism in relation to the performance of the system and the circumstances in which it operates. For example, it may be necessary to test whether a production controller continues to adjust the production level when he should, or to determine whether the stimuli that activate the controller are adequate to deal with the situation, and whether control should be transferred to another controller better equipped to react to changes in the system. Such an arrangement that calls for the controller's performance to be under scrutiny can be termed "control of control".

Linkages between Multi-controllers

The linking of several identical controllers is called first order control, and is characterized by all the con-

trollers having equal status and opportunity to affect the state of the system. This does not happen when non-identical controllers are linked, because these are designed to react to different stimuli, and so may not have equal opportunity to react. In some cases the linking of two non-identical controllers leads to second order control, in which one controller acts most of the time and the other only some of the time, or when the first controller fails.

I shall discuss three types of control linkage: control in series, control in parallel and conjoint control. These are significant in the way they can impose—or are prevented from imposing—their will on the system, and in the way they affect the probability of breakdown of the system.

Table 1 shows the way in which a controller that can assume two states, ON or OFF, actually responds compared with the way he should respond. There are two types of failure: type 1, failure to switch ON when required, and type 2, failure to switch OFF when required. When considering the effect of the control procedure on the probability of failure it is important to remember the distinction between these two types of failure, for each may be affected in a different way by the control linkage that is adopted.

Table 1. TYPES OF FAILURE TO RESPOND

The way controller(s) should respond	Controller(s) actual response	
	ON	OFF
On	No failure	Failure 1
Off	Failure 2	No failure

First Order Controllers in Series

An example of first order controllers in series is provided by an electric boiler with its temperature controlled by two identical thermostats connected in series (Fig. 1a). If both are working properly and switched on and off at the same temperature, the control procedure is just as effective with one perfect control mechanism. But if one thermostat fails to switch OFF, the electric circuit is broken by the other, and vice versa.

But the performance of the boiler may well depend on the type of failure of the thermostats. As long as this failure occurs in switching OFF, the reaction of one thermostat effectively compensates for the sluggishness or complete breakdown of the other. But if both thermostats are at the OFF position and the temperature declines

to the point where the current should be switched on again, and if one thermostat now fails to react, the system will remain OFF whatever the other thermostat does.

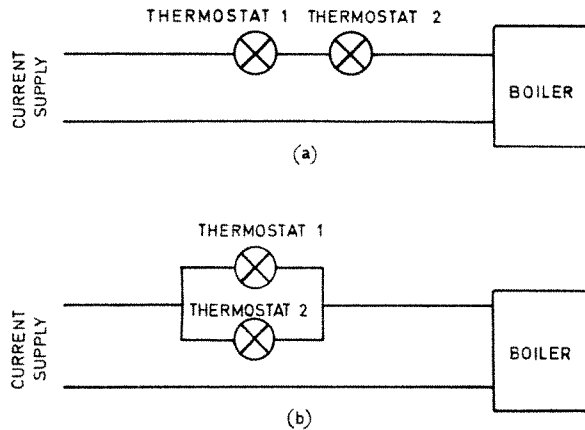

Fig. 1. Two control linkages. (a) Control in series; (b) control in parallel.

For control to be effective in this case, therefore, it is sufficient for only one thermostat to switch OFF but essential that both switch ON. If the probability of failure to switch OFF when required is p_0 for each thermostat and if p_1 is the probability of failure for each to switch ON, then the operation of the two-thermostat system is described by the probabilities in Table 2. The probability that the system is not switched OFF when it should be is $P_0 = p_0^2$, whereas the probability that it is not switched ON consists of the probability that thermostat 1 fails when 2 does not, $p_1(1-p_1)$; the probability that thermostat 2 fails when 1 does not, $p_1(1-p_1)$; and the probability that both fail, p_1^2 . In other words, the probability P_1 that the system is not switched ON when it should is

$$P_1 = p_1^2 + 2p_1(1-p_1) = p_1(2-p_1)$$

When p_1 is sufficiently small (say, less than 0.1), p_1 in the parentheses is negligible and the probability of failure to switch ON is approximately $2p_1$.

Table 2. FAILURE OF TWO THERMOSTATS

Thermostat 2		Thermostat 1	
		Need to switch OFF	Need to switch ON
		Failure p_0	Function- ing $1-p_0$
		Failure p_1	Function- ing $1-p_1$
Need to switch OFF	failure	p_0^2	$p_0(1-p_0)$
	functioning	$p_0(1-p_0)$	$(1-p_0)^2$
Need to switch ON	failure	p_1^2	$p_1(1-p_1)$
	functioning	$p_1(1-p_1)$	$(1-p_1)^2$

Thus the introduction of a second control mechanism provides an excellent insurance against overheating, but sometimes coupled with almost double the chance that the system will cease to operate (Fig. 2). In the case of a water-boiler this may be justified, but when it is undesirable that a complete shutdown is so likely to occur, control mechanisms may have to be redesigned to reduce p_1 , and with a moderate increase in p_0 the overall effect is generally beneficial. This applies to any system in which flow is controlled by mechanisms coupled in series. If the

mechanisms are valves which adjust the rate of flow of a liquid to any level up or down the scale, and not necessarily only to ON-OFF positions as in the thermostat, the governing factor is always the valve that allows the lowest rate. Failure to decrease the flow p_0^n for n valves and failure to increase it is $1 - (1-p_1)^n$ and when p_1 and n are sufficiently small this expression is approximately equivalent to np_1 .

The administrative analogy to the control system described here is a chain of executives, who function in sequence with relation to any set of operations they control. Consider the case where expenditure needs the authorization of two executives, both equal in status and unaffected by the behaviour of the other. Control is in series when authorization is conditional on both executives affirming their signatures on a requisition form (that is, both must be at the ON position), while only one needs to object to stop the expenditure (this executive being at the OFF position). The same procedure is prevalent with a cheque which requires two signatures: it can be cashed when the two signatures are ON; it is worthless if any one signature is OFF.

Fig. 2. Failure of system to switch OFF (P_0) or ON (P_1) for two controllers in series.

Another administrative example is provided by a flow of progress reports which is subjected to the scrutiny of several executives. Each may pick on an item in the reports and start an inquiry or issue instructions for modifications, or stop production. He can be said to be acting in a manner analogous to the thermostat that switches the circuit off. All the executives must acquiesce or raise no questions (or not read the reports) for no action to be taken, and this is when they are said to be at the ON position. But there is a significant difference between this situation and the case of the cheque: here ON is indicated by the *absence of reaction* on the part of the executive, whereas with the cheque, ON requires his *active response*.

Using the multi-thermostat analogy I propose the following definition for the administrative system. In a system in which control is exercised by the intensity of a signal or by two types of action, several control mechan-

isms are said to be operating in series if one action is triggered off by at least one mechanism, but the other action is enforced by all the mechanisms, and these actions of the mechanisms may be called OFF and ON respectively. The terms ON and OFF are used for convenience; they need not literally convey the connotation of switching operations. In the adjustment of, say, a production level, these activities may relate to pushing the level upwards or downwards, but by my definition "upward" indicates ON only if all control mechanisms are in agreement. If a procedure is set up whereby an increase in production rate is effected by one controller only, and a decrease by all controllers, then the first is equivalent to OFF and the latter to ON.

Controllers in Parallel

When controllers are connected in parallel, each can "activate" the system alone. In contrast to a linkage in series, where all the controllers need to be ON for the system to be ON but only one controller needs to be OFF for the system to be OFF, a linkage in parallel requires only one controller to be ON for the system to be ON but all the controllers have to be OFF for the system to be OFF. Switches in electrical circuits can be wired in series or parallel, and the type of linkage adopted has the implications that I have just described as to whether unanimity of agreement between the controllers is required for the system to change its mode of activity.

Table 3. SUMMARY OF PROBABILITY OF FAILURE

	Type 1 (Failure to switch ON) P_1	Type 2 (Failure to switch OFF) P_0
One controller	p_1	p_0
Two controllers in series	$p_1(2-p_1)$	p_0^2
Two controllers in parallel	p_1^2	$p_0(2-p_0)$

In the case of a water boiler controlled by two identical thermostats connected in parallel (Fig. 1b), if the probability of failure of either thermostat to switch OFF when it should is p_0 and its failure to switch ON is p_1 , then the probability of failure of both is given in Table 1. But because both thermostats have to act to switch the boiler OFF, the probability of failure for the system to switch OFF is

$$P_0 = p_0(2 - p_0)$$

whereas the probability of failure to switch ON is

$$P_1 = p_1^2$$

The position is therefore reversed (Table 3). If in Fig. 2 the graphs labelled P_0 and P_1 are relabelled P_1 and P_0 respectively the probability of failure for the linkage in parallel is obtained. Clearly control in parallel achieves the opposite effect of control in series—it provides a better protection from failure (compared with the single controller) to switch ON, but a poorer protection from failure to switch OFF. Thus the choice between the two control procedures may depend on the type of failure considered to be the most desirable to avoid.

For example, if when authorizing payment (or expenditure) two executives are assigned to handle the relevant documents and if it is thought that each should be allowed to authorize payment on his own, they are linked in parallel. When it is necessary to ensure a closer scrutiny

of the documents (particularly when large sums of money are involved) and reduce the risk of authorization being made by mistake, both executives may have to agree to the expenditure; they are then linked in series. But as I have shown, improved protection achieved in this way is coupled with an increased risk that managers will be over-cautious and fail to authorize justified expenditure.

Transactions at counters (such as payment of bills or purchase of merchandise) provide another example of a choice between linkage in series and parallel. When the volume of business necessitates several counters, the transactions are often organized as control in parallel. A transaction is offered by a customer to the controller manning the counter and, if the controller approves, the transaction goes through; if he is linked in parallel to the other controllers at other counters, he need not consult any of them. If the customer is dissatisfied with the decision, he can try another counter. Only when all controllers that are connected in parallel reject the customer does the transaction not take place. The implication in choosing this type of control for counters is that the penalty for type 2 failure (Table 1) is small, compared with the need to provide prompt service, and therefore the increased risk of incurring type 2 failures by introducing control in parallel can be tolerated.

A third example of a choice between linkages is provided by components that have to be inspected after leaving a production line. If the volume of production is large, and if the utility of a component is not excessive (for example, its monetary value or its future function), inspectors are often linked in parallel. As in the previous example, each inspector can "pass" the components; but if a component fails to pass one inspector, it can be sent to another (or even back to the same inspector) and there is, of course, a chance that it will pass the second time. Operators and inspectors know that this procedure increases the probability of components passing through when perhaps they should not, but in most cases the alternative of control in series is considered too costly and time consuming.

Conjoint Control

When control mechanisms are linked in series, it is sufficient for one to be at the OFF position for all the others to be neutralized. (This is reminiscent of the power of veto; members of a committee who have this power can be said to act as controllers in series, and any one member can prevent the others from taking action.)

To enable each controller to activate the system without the acquiescence of the others, controllers have to be connected in parallel, as I have described, but an activity cannot then be stopped without the agreement of all the controllers. And so control in either series or parallel requires the collaboration of the controllers.

A mode of control that allows each controller to act on his own, irrespective of whether activity needs to be started or stopped, can be called "assertive controllers in parallel", or better "conjoint controllers". In this case whenever one controller acts, it is as if the others automatically acquiesce with his decision and all controllers act together.

A lighting circuit with two switches has two conjoint controllers: each switch can switch the light ON or OFF on its own, irrespective of the state of the other switch. It is no longer necessary for both switches to act for the

light to be on and each switch can be regarded as automatically activating the other; when one goes on it overrides the other, and vice versa. The advantage is obvious: the system can continue to operate even if one controller breaks down. Unlike the system with several controllers in series or in parallel, which continues to operate for one type of breakdown but fails with another, a system with conjoint controllers will function as long as at least one controller is operational.

The distinction between the three types of control linkages discussed here is not solely characterized by the way information flows in the system, but also by the way controllers can affect each other. In administrative systems information may flow (documents or data) from one executive's tray to another, and in this case there may be a delay between decisions, and controllers further along the line may know how previous controllers have acted, or failed to act, in given situations. This type of information flow requires the controllers to act in sequence, and I have discussed the significance of such a mode of control before¹.

In the other form of information flow data are presented to the various controllers simultaneously, or at least when a controller is faced with the problem of making a decision, he does so without any previous knowledge of the decisions made by his fellow controllers. Thus, even if the information is not presented to all of them simultaneously, and if the decisions are not made at the same moment, the fact that each controller makes his decision on his own (he may speculate as to how the others have or will react, but he does not know for sure) means that this case can be treated as if controllers make their decisions simultaneously.

An important distinction between the three control procedures in the case of simultaneous decisions is that when linkage is in series or parallel each controller acts on the system but not on the other controllers, whereas in conjoint control each controller's actions automatically lead the others to acquiesce. In the first two, disagreement between controllers or failure of one can cause the system to get out of control (for example, shut down); in the third, disagreement manifests itself in the fact that each controller can always have the last word.

In each of the three procedures controllers have equal status. Each can affect the other in the same way, although one can prove to be more of a nuisance to the others in his actions, or failure to act when he should. Nevertheless, no controller dominates the scene or is able to dictate to his fellows, irrespective of prevailing circumstances. Even in conjoint control, when any controller can overrule the others, his action holds only as long as the others agree with him, otherwise the effect of his decision can be annulled by a counter-decision of another controller. Conjoint control does not have a power of veto vested in the individual controllers, as with control in series or in parallel. The power that each controller has to affect the state of the system and the limitations that his fellow controllers can impose on him are very different in the various control procedures. Nevertheless, when decisions are made simultaneously all controllers have an equal opportunity to affect the outcome for the system and it is in this sense that they have equal status.

Second Order Controllers

So far I have been concerned with the coupling of essentially identical control mechanisms, namely, mechanisms

designed to react to the same stimuli. The purpose of more than one controller, as I have shown, is to provide better protection against some kind of breakdown than is possible with one controller. Another way to achieve this is to link non-identical control mechanisms designed to react to different feedback signals regarding the performance of the system. In this way, two controllers can be set to respond with different frequencies, one looking after the system most of the time, while the other is required to act only when the need arises. This is second order control.

The principal difference, therefore, between several controllers acting within a first order or a second order procedure lies in the frequency with which the second mechanism needs to operate. If, for example, a mechanism is known to deteriorate the more it is activated, perhaps because of wear of its component parts, then the second order procedure may be advantageous. If, however, both mechanisms deteriorate with time, irrespective of how frequently they switch ON and OFF, the first order arrangement has the advantage of providing a better control (say, of a temperature level within closer limits) without loss of time-dependent reliability.

It should be pointed out that the type of failure of any one mechanism is just as important in a second order arrangement as in a first order arrangement. In other words, control can continue to be exercised when one mechanism fails to switch OFF; if either remains at the OFF position and fails to switch ON, the whole system is put out of action. The probabilities for failure (Table 3) are therefore equally applicable to a second order control system.

Second Order Control in Series

If two identical thermostats are linked to control the temperature of the water in a boiler, both are expected to react at the same time, but if the two are coupled so that one is set to react at two given temperatures and the other is set at more liberal levels (that is, the range between the two levels of the latter includes the two levels of the former), then the second thermostat only has to react when the first fails, and a second order control is established. In Fig. 3, thermostat 1 is designed to switch off at temperature L_1 and to switch on at l_1 , while thermostat 2 is designed to react similarly at L_2 and l_2 respectively.

In Fig. 3a and b the relationship between these control temperatures is

$$L_2 > L_1 > l_1 > l_2$$

In Fig. 3a thermostat 1 is master of the situation for a while, during which thermostat 2 is switched ON. Then at one point thermostat 1 fails to switch OFF when the temperature reaches L_1 , so that when it reaches L_2 thermostat 2 intervenes, and as long as thermostat 1 is out of action, thermostat 2 acts as a first-line controller, except that the temperature now fluctuates between l_2 and L_2 , rather than between l_1 and L_1 as before. Thermostat 1 later returns to action and reacts at L_1 and thermostat 2 assumes a passive role, until required again. But this depends on the kind of failure thermostat 1 is subjected to. In Fig. 3a it fails to switch OFF and so allows thermostat 2 to take over. In b, however, it fails at one stage to switch ON and when the temperature eventually falls to l_2 thermostat 2 cannot save the situation because 2 is ON

in any case and the linkage in series requires both to be on for an electric current to flow to the boiler.

In Fig. 3c the control levels are arranged as $L_2 > L_1 > l_2 > l_1$ and the ranges overlap, but the control procedure is unaffected. Thermostat 1 acts as a first-line controller for a while and the temperature fluctuates between l_1 and L_1 . At point 1 thermostat 1 fails to switch off and

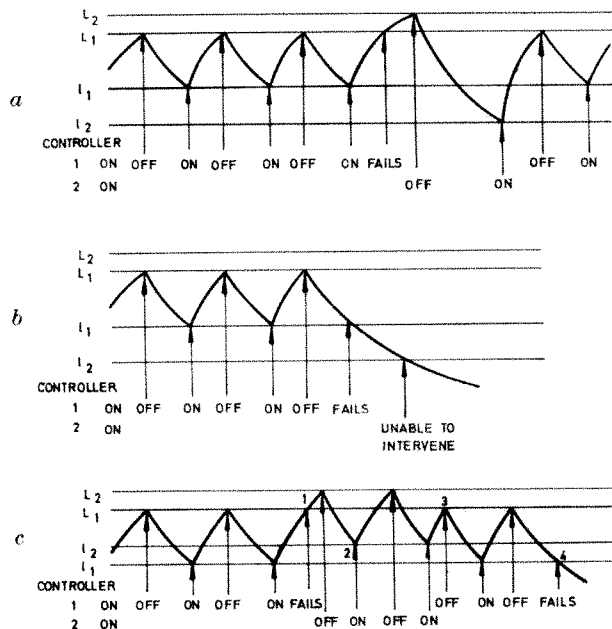

Fig. 3. Second order control in series.

thermostat 2 takes over and switches OFF at L_2 . When the temperature declines to l_2 thermostat 2 (point 2) switches ON and continues to act as long as thermostat 1 is out of action, with the temperature now fluctuating between l_2 and L_2 . At point 3 thermostat 1 is again operational as a first-line controller, but when it fails to switch ON at point 4 thermostat 2 cannot intervene and the temperature continues to decline below the desirable limit. There is, then, essentially no difference between the case where the control levels do not overlap (Fig. 1a and b), and the case where they do (Fig. 3c).

Second Order Control in Parallel

The effect of linking the two thermostats in parallel is shown in Fig. 4. The case $L_2 > L_1 > l_1 > l_2$ is shown in a and b. In a the first order thermostat is in operation, while the other thermostat is off. Then at one point the first order controller fails to switch ON and when the temperature declines to l_2 the second thermostat is activated. As in a linkage in series, the temperature fluctuates between l_1 and L_1 when the first order thermostat is in control and between l_2 and L_2 when the second order thermostat takes over. In Fig. 3c the control levels are $L_1 > L_2 > l_1 > l_2$ and, again, as long as controller 1 is operational, the temperature fluctuates between l_1 and L_1 , but when controller 2 starts to act the fluctuations are between l_2 and L_2 .

The difference between the linkage in series and the linkage in parallel lies, as I have shown, in the type of

failure of the first order controller that causes the whole system to run out of control. With linkage in series the system can tolerate the failure of the first order controller to switch OFF, but it shuts down if this controller fails to switch ON, as Fig. 3b shows. With linkage in parallel the position is reversed: a failure of the first order controller to switch OFF can be tolerated, but if he fails to switch ON, the second order controller is powerless to intervene.

Clearly, if a linkage in series is adopted, it is necessary to minimize the risk of the first order controller committing a failure of type 1 (Table 1). This can be achieved by designing the controller with a low p_1 (=probability of failure to switch ON when necessary). Alternatively, by coupling two (or more) controllers in parallel to act together as a first order controller, the probability of failure to switch ON is drastically reduced (Table 3) and, when this parallel linkage is connected to a second controller in series, the risk of a complete breakdown (Fig. 3b) is reduced.

Fig. 4. Second order control in parallel.

Similarly, if a linkage in parallel is adopted between a first and a second order controller, it is desirable to avoid a situation such as shown in Fig. 4b, by replacing the single first order controller by two (or more) identical controls linked in series.

Conjoint Control

The operation of two non-identical thermostat controllers linked in conjoint control is shown in Fig. 5. In a $L_2 > L_1 > l_1 > l_2$ and the temperature fluctuates between l_1 and L_1 as long as the first order controller does not fail to act. When it does, the second order controller steps in and the temperature fluctuates then on the type of failure that the first order mechanism is subject to. If it fails to switch OFF, the control limits become effectively l_1 and L_2 ; and if it breaks down completely, the control limits are l_2 and L_2 . The failure of the whole system depends only on the failure of the second order controller,

and in this respect conjoint control differs fundamentally from the examples shown in Figs. 3 and 4.

Another mode of operation of first order and second order conjoint controllers is illustrated by two pairs of sieves through which beads of varying sizes are passed. (The beads are analogous to signals about the performance of the system.) The first order controller is represented by one pair of sieves: one sieve is for the lower limit, which removes beads that are too small; those that do not pass through this sieve are processed through another, which stands for the upper limit and does not allow too large beads to pass. If the second order controller is represented by another pair of sieves, one with holes smaller than the corresponding lower limit sieve of the first order and one with holes larger than the corresponding larger limit sieve, the second pair will not remove any beads if the first pair functions properly. But if the first order controller fails, or is removed, the second pair of sieves operate as if they were a first order controller, only the size of beads that are passed will fluctuate more widely than when the first original pair of sieves is used.

Fig. 5. Conjoint control.

Another type of conjoint control is illustrated in Fig. 5b where the control limits are such that $L_2 > L_1 > l_2 > l_1$. Here, in the absence of failure, controller 1 acts when the temperature reaches L_1 and controller 2 acts when it declines to l_2 . Thus the control function is shared by the two controllers: one guards against overheating, the other against overcooling. In this case, neither is a first order controller throughout, although each has a function attributable to a first order controller. Similarly, neither is a second order controller throughout, although each can act when the other fails. This mode of control can be called hybrid control.

Conjoint control can therefore take three forms: first order, when all controllers are essentially identical with respect to the stimuli to which they react; second order (or higher) when another controller takes over whenever the first order controller fails, and hybrid, when each controller performs functions of both first order and second order control.

The definitions of first and second order control and the examples cited earlier lead to several conclusions. (1) Two controllers acting on double action limits (Figs. 3, 4 and 5) are equal if $L_1 = L_2$ and $l_1 = l_2$ and the controllers are then

first order. (2) If a second order controller is identified in a system there must be at least one first order controller. If the latter breaks down, or is removed from the system, the second order controller takes over. (3) If two controllers are linked in series or in parallel the risk of certain failures in the control function is greatly reduced, compared with the single controller system, but the risk of a complete failure is increased (Table 3). If there is a second order controller this risk can be greatly diminished when the first order controller is replaced by two or more identical controllers linked in an appropriate way. (4) Hybrid control is a particular feature that can be built into conjoint control, but not into control in series or control in parallel. (5) Hybrid control can cause the system to be very tightly controlled and in administrative systems this can lead to acute frustration for controllers and the controlled.

Hierarchical Control

Hierarchy in an organization is often identified as an authority vested in one management level to intervene at another level and overrule decisions. As I have shown, even in pure series and parallel linkages of first order control each controller has some power over his fellow controllers, in the sense that he can, in certain circumstances, prevent the others from acting. It is useful therefore to define a hierarchical relationship between two controllers as allowing one controller to override another, but not vice versa. In other words, there is a distinction between the case when the overruling procedure is mutual for the two controllers (as in first order control) and when it is one sided.

In this respect second order control demonstrates some facets of hierarchical relationships, manifest by the fact that a second order controller need not act as frequently as a first order controller. The second order controller need not even monitor continuously the performance characteristics of the system or all the decisions of the first order controller, and arrangements can be made for certain cases only to be referred to the second order controller.

Second order control in series or in parallel gives the first order controller the power to lead the system to a state beyond the control of the second order controller. The power of intervention of the second order controller is therefore limited, as Figs. 3 and 4 show. On the other hand, the second order conjoint control allows the second order controller to intervene whenever the first order controller fails.

Another way in which hierarchical control can be designed is for control to be transferred from one controller to another, when certain symptoms in the operating characteristics of the system are unravelled. The procedure for general practitioners to refer patients to specialists or to hospitals is one such example. The decision to transfer the patient lies with the general practitioner; in other words the controller himself is responsible for identifying the circumstances in which he brings in another controller. In other cases the decision to transfer control may rest with a separate controller.

The types of linkage I have discussed are only three of many procedures that can be designed, but they illustrate well the way in which linkage between controllers can affect the relations between controllers and systems and interrelations between controllers.

Scattered Arrangement of the Bacterial Ribosomal Cistrons

by

I. PURDOM
J. O. BISHOP
M. L. BIRNSTIELEpigenetics Research Group,
Institute of Animal Genetics,
University of Edinburgh

In two bacterial species the tandem genes coding for 23S and 16S ribosomal RNA are widely scattered, by contrast with the situation in eukaryotes.

In both prokaryotes and eukaryotes, ribosomal cistrons occur as multiple genes. The only exception so far is the genome of *Mycoplasma*¹ which contains a single ribosomal cistron. In eukaryotes the ribosomal DNA complements are tightly clustered in the nucleolar organizer region(s) of the chromosome^{2,3}. The study of ribosomal DNA in *Xenopus laevis* and *Drosophila melanogaster* has shown that the 28S and 18S ribosomal DNA segments occur closely linked⁴⁻⁶ and that the nucleolar organizer DNA is made up from many linked repeats of such tandem genes⁴ together with spacer DNA which does not code for ribosomal RNA^{4,5,7,8}.

The bacterial 23S and 16S cistrons occur also as tandem cistrons⁹. Yankofsky and Spiegelman¹⁰ were first to propose a clustering of the ribosomal cistrons on the bacterial chromosome. Their hypothesis was borne out by observations that in both *Bacillus subtilis*¹¹ and *Escherichia coli*¹², ribosomal cistrons are located in two discrete regions of the genetic map. But less than 1 per cent of bacterial DNA is ribosomal DNA. The methods which have been used so far are unable to distinguish whether the several tandem pairs of 16S and 23S cistrons in each region are close together or scattered. Here we show that in at least two bacterial species the tandem pairs are quite widely scattered, by contrast with the situation in eukaryotes.

In the more commonly studied bacteria, ribosomal RNA has a GC content of some 53 per cent¹³ and from this one deduces that the ribosomal cistronic DNA in these bacteria bands in CsCl at a density of 1.710. In most of these bacteria the chromosomal DNA differs in overall GC content from that of ribosomal RNA. In these instances chromosomal DNA and ribosomal cistronic DNA have different buoyant densities. We shall show that this is the case, for example, for *Proteus mirabilis* (1.700), *Serratia marcescens* (1.718) and *Micrococcus lysodeikticus* (1.731 g cm⁻³) DNA. Bacterial ribosomal cistrons tend therefore to be embedded in genomic DNA of quite different buoyant density characteristics. This property can be used to study the degree of clustering on the chromosomal DNA.

Just under 0.4 per cent of the DNA extracted from an exponentially growing culture of *E. coli* K12 becomes hybridized with saturating amounts of ribosomal RNA¹⁴. In exponential growth (50 min generation time) the DNA content per genome is 1.4 times the genetic complexity¹⁵, so that this corresponds to $0.008 \times 1.4 \times 2,700 \times 10^6 = 30 \times 10^6$ daltons of (double stranded) DNA or ten copies of the ribosomal DNA cistrons. If we make the conservative assumption that all of the ribosomal DNA can be detected by hybridization and that the average position of the cistrons is halfway along the chromosome from the origin of replication, we can calculate that there are about seven copies of the ribosomal DNA cistrons per chromosome. If these are located in two regions in approximately equal numbers, each region contains three or four copies. Let us consider two extremes. First, all the ribosomal cistrons in each region are clustered together without intervening DNA. Because the amount of rRNA

corresponding to one tandem is about 3×10^6 daltons, three or four contiguous copies make up 9×10^6 – 12×10^6 daltons. Second, the three or four rDNA tandems in each region are widely separated by unrelated DNA sequences.

Whether we liberate pure ribosomal cistronic DNA fragments in these two cases will depend entirely on the size to which we fragment the chromosomal DNA. In the first case (Fig. 1a), fragmenting the DNA to, say, 6×10^6 dalton stretches will liberate nearly all rDNA free from other DNA, and only little ribosomal DNA will remain attached to other DNA. In the second case (Fig. 1b), 6×10^6 daltons are still enough to contain both ribosomal and intercalated DNA, in about equal proportions, and the overall buoyant density of the fragment would then be shifted towards that of the average genomic density position. To liberate pure ribosomal cistronic DNA in this case the DNA would have to be reduced in size to subcistronic levels.

To elucidate the nature of gene linkage of the bacterial ribosomal cistrons we banded bacterial DNA on CsCl gradients. We determined the position of the rDNA containing fragments on the gradient by challenging the fractions along the gradient with ³²P-labelled rRNA. In all gradients we included also a minute amount of *E. coli* ¹⁴C-DNA, for this bands at 1.710 as liberated bacterial rDNA should.

First we tested the proposition that pure bacterial cistronic DNA bands at 1.710 g cm⁻³. To eliminate any problems that might arise from gene linkage we sonicated the bacterial DNA to subcistronic levels (MW about 5×10^5 daltons) before centrifugation. Fig. 2a–c illustrates the outcome of the CsCl fractionation and hybridization experiment for *Proteus*, *Serratia* and *M. lysodeikticus* DNA. In all cases the ³²P-rRNA/DNA hybridization activity coincides more or less closely with that of the *E. coli* ¹⁴C-DNA marker, as expected. At the other extreme, when DNA has been prepared gently to avoid excessive fragmentation and banded on CsCl density gradients, it may be seen that the hybridization activity is close to that of the bacterial DNA as a whole (Fig. 3a–c). In these DNA preparations the ribosomal cistrons are still knitted in with other DNA.

Fig. 1. Arrangement of the ribosomal 23S + 16S tandem genes.

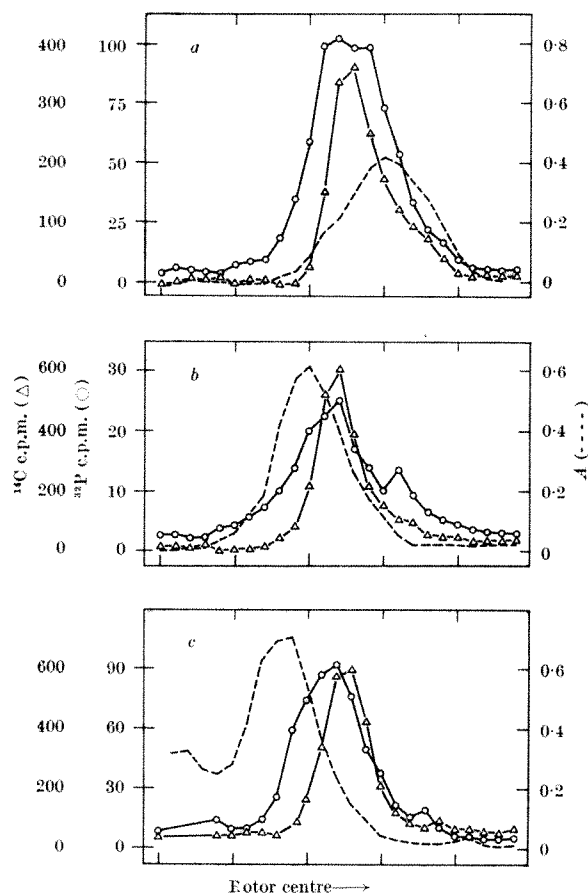

Fig. 2. Isopycnic centrifugation of liberated ribosomal cistrons. 100–150 μ g DNA was sonicated to a molecular weight of about 0.5×10^6 daltons and banded with 2 μ g *E. coli* ^{14}C -DNA in a CsCl density gradient (gradient B, ref. 4). Each gradient fraction was bound to membrane filters as described⁴ and challenged with 1–2 μ g/ml. *Proteus*, *Serratia* or *M. lysodeikticus* rRNA ($> 3 \times 10^4$ c.p.m./ μ g) in $6 \times \text{SSC}$ at 70°C for 2 h. The filters were treated with ribonuclease, washed by the batch method⁴ and radioactivity was counted. a, *Proteus* DNA; b, *Serratia* DNA; c, *M. lysodeikticus* DNA.

The banding of the rDNA with the remainder of the chromosomal DNA is not caused by an artefactual entrapment of ribosomal cistronic DNA. This can be seen in three ways: (1) the *E. coli* ^{14}C -DNA separates and attains its appropriate buoyant density, even when high molecular weight DNA is used; (2) reduction of the amount of DNA (5 μ g in Spinco angle rotor, No. 40 tube) yields an identical buoyant density for rDNA, and (3) when both *Xenopus* DNA (MW 25×10^6) and *Proteus* DNA (MW 7×10^6) are banded together (Fig. 4) the polycistronic *Xenopus* rDNA bands at 1.724 g cm^{-3} (ref. 4), while *Proteus* rDNA of intermediate size bands at intermediate buoyant density (1.705) between 1.712 (fully liberated) and 1.701 g cm^{-3} (fully integrated cistrons).

We have studied *Proteus* DNA at various stages of fragmentation. Fig. 5 summarizes these experiments. The average molecular weight of the *Proteus* DNA fragments is plotted against the average density of the rDNA-containing DNA segments. DNA which is smaller than 1.5×10^6 daltons contains DNA which bands like, or slightly heavier than, *E. coli* DNA (Fig. 2a). In DNA of 7×10^6 daltons the rDNA is obviously still contaminated by low density DNA (Figs. 4 and 5). Clearly the ribosomal tandem cistrons of *Proteus* are not clustered together, but are clearly spaced by other chromosomal DNA. Were this spacing relatively moderate, one might hope to arrive at a situation in which one could isolate serial repeats of intercalated and ribosomal tandem genes, as in rDNA of *Xenopus*⁴, and this would lead to a temporary levelling off and formation of a shoulder in the density shift. From

our results it seems that the first discernible levelling off occurs only in DNA with a molecular weight of the order of 30×10^6 . This, and the fact that in high molecular weight DNA the rDNA containing fragments band very close to the DNA as a whole, must mean that the length of the intercalated DNA is considerable. By balancing the density of the high density ribosomal cistrons against the low density chromosomal DNA we may estimate the approximate amount of intercalated DNA. If the intercalated DNA were to be made up from pure AT segments it would amount to 10×10^6 daltons. If it is of average base composition, the amount would be increased to 30×10^6 daltons.

The presence of intercalated DNA may also be detected in *Serratia* by hydroxyapatite fractionation. By this technique the compositions—but not the mass—of the intervening DNA can be determined. Because *Serratia* DNA is on average richer in GC than is *Serratia* rDNA it should be possible to choose a temperature of incubation at which ribosomal cistronic DNA is rendered single stranded while maintaining the spacer DNA in double strand form. The denatured DNA, if free from native DNA, may then be selectively eluted from the hydroxyapatite column and challenged with radioactive ribosomal RNA.

Fig. 6 shows thermal chromatograms of *Serratia* DNA at single stranded molecular weights of 0.7×10^6 , 1.5×10^6 and 6.6×10^6 daltons. 50 per cent of the ribosomal cistronic DNA is eluted at 92°C when the DNA is fragmented to sub-

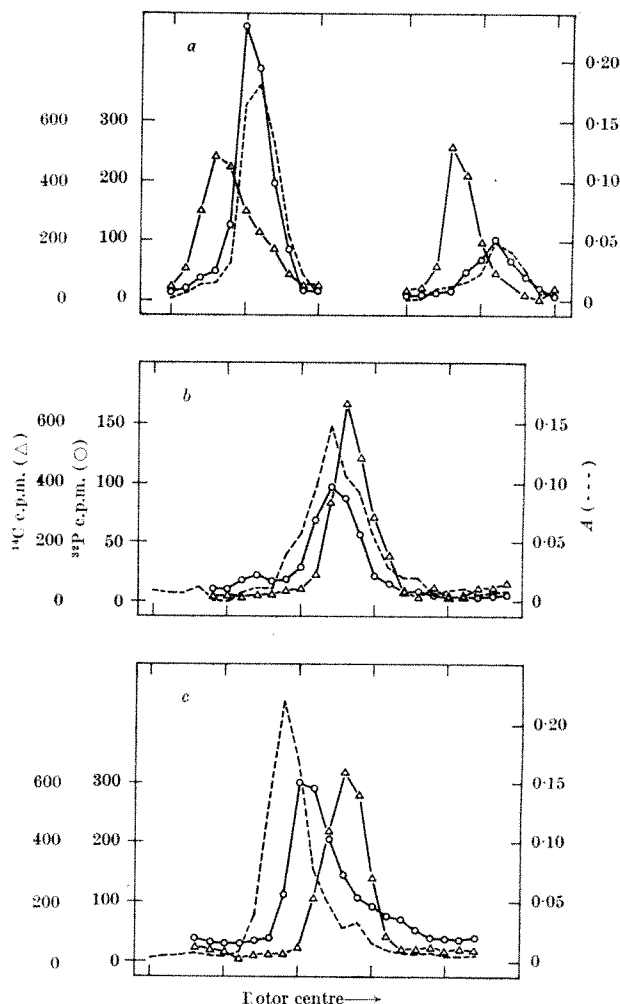

Fig. 3. Isopycnic centrifugation of integrated ribosomal cistrons. Conditions of centrifugation and hybridization as in Fig. 2, except that 50 μ g DNA was used for each gradient. a, 50 μ g (left) and 5 μ g (right) *Proteus* DNA about 70×10^6 ; b, *Serratia* DNA; c, *M. lysodeikticus* DNA.

Fig. 4. Simultaneous banding of rDNA from *Xenopus laevis* and *Proteus mirabilis*. 25 μ g *Xenopus* DNA (MW 2×10^7) and 25 μ g *Proteus* (MW 7×10^6) were centrifuged together on gradient B* and challenged as described in Fig. 2, except that the hybridization mixture was incubated at 55°C and contained 50 per cent formamide, 6 \times SSC, 2 μ g/ml. *Xenopus* 3 H-rRNA (1.5×10^4 c.p.m./ μ g) (●—●) and 1 μ g/ml. *Proteus* 32 P-rRNA (○—○). A, *Xenopus* rDNA (1.724); B, free bacterial rDNA; C, *Proteus* and *Xenopus* DNA (1.698–1.700 g cm $^{-2}$).

cistronic levels: this is 4°–5° C below the temperature for the rest of the DNA. At 6.6×10^6 daltons, however, the elution profile of the ribosomal DNA sequences approximates that of total DNA, while at 1.5×10^6 , elution of the ribosomal cistronic DNA occurs at intermediate temperatures. At 6.6×10^6 daltons, melted ribosomal cistronic DNA is still physically linked to native DNA and thus retained on the column. Because the temperature necessary to elute rDNA in these conditions is close to that required to recover the main body of *Serratia* DNA it follows that the spacer DNA, at least in the vicinity of the ribosomal cistrons, must be of mean average base composition, that is, 58 per cent GC. Single stranded fragments of 1.5×10^6 daltons correspond exactly to a length of DNA sufficient to code for one 23S and 16S RNA. There is no reason to suppose that DNA breakage during shearing occurs only at the beginning or the end of the ribosomal tandem cistrons, so that 1.5×10^6 daltons stretches of DNA contain ribosomal cistronic DNA of varying purity and consequently with a chromatographic behaviour intermediate between the two extremes.

Xenopus laevis^{4,5,7,8} and *Proteus mirabilis* rDNAs resemble each other in that the ribosomal RNA sequences are interspersed with other DNA. In both cases the additional DNA is in large excess of the extra DNA necessary to account for the observed rRNA precursor. The precursor in *Xenopus* is 14 per cent larger than the sum of 18S and 28S RNA⁴, and in bacteria the relative difference is probably less^{16,17}. Here the resemblance ends. In the case of *Xenopus* the additional DNA is 1.2 times greater¹⁸ than or equal⁸ in quantity to the ribosomal cistronic DNA and has a very atypical base composition⁸. In the case of the bacteria the intercalated DNA seems to have average base composition, and is probably of the order of ten times greater in quantity than the rDNA.

Fig. 5. Banding position of ribosomal DNA complements from *Proteus mirabilis* as a function of the molecular weight of the DNA. *Proteus* DNA was sheared or sonicated to various molecular weights, banded on CsCl gradients and challenged with 32 P-rRNA as described in Fig. 2. The mean density of the rDNA was determined for each preparation and plotted against the average molecular weight of the DNA preparation.

No function has hitherto been found for the bulk of the spacer DNA in *Xenopus*. In the case of bacterial rDNA the situation could be rather different. If we take three as a conservative estimate of the number of rDNA tandem cistrons located in the region of the *str* locus, then they span together with the intervening DNA a total DNA length of at least 30×10^6 daltons, corresponding to 1.1 per cent of the length of *E. coli* chromosomes or about 1.1 minute of map distance. In *E. coli* the region of the map around *str* contains a large number of known genetic loci¹⁹. It is therefore highly probable that some bacterial genes are located in the DNA regions which lie between the rDNA cistrons. The same may be true of *B. subtilis*. Smith *et al.*¹¹ have suggested that the rDNA cistrons are scattered in the region of *str*. Experiments which show that the DNA of the *str* gene and adjacent genes is rather resistant to thermal denaturation²⁰ suggest that these genes are closely associated with ribosomal cistronic DNA.

Our finding of the discontinuous arrangement of bacterial cistrons can also explain the difficulties encountered in attempts to isolate native ribosomal cistrons in pure form from bacteria^{21,22}. By contrast with *Xenopus*, where rDNA is a discrete DNA segment which can be separated with great ease from other DNA⁴, bacterial ribosomal DNA complements are necessarily more prone to be contaminated by chromosomal DNA. More sophisticated procedures for the isolation of native ribosomal cistrons from bacteria than those hitherto used are obviously required.

Fractionation and Hybridization of the DNA

The bacterial cells were lysed in 0.15 M NaCl–0.1 M EDTA–1 per cent sodium lauryl sulphate and deproteinized according

Fig. 6. Thermal chromatogram or hydroxyapatite columns of *Serratia* DNA at various molecular weights. 1 mg *Serratia* 14 C-DNA (630 c.p.m./ μ g) in 0.12 M phosphate buffer was bound to a 2×2 cm hydroxyapatite column²¹ at 70°C. The temperature was gradually raised and the denatured DNA eluted with 3×5 ml. 0.12 M phosphate buffer at 89–98°C in 1°C increments. 12 ml. of each fraction was denatured by addition of 1/10 volume of 1.44 N NaOH. 1/10 volume of 1 N H_3PO_4 together with 3/10 volume 20 \times SSC were added and the solution was passed through 'Millipore' filters. The immobilized DNA was reacted with 10 μ g/ml. *Serratia* 32 P-rRNA (8×10^4 c.p.m./ μ g) in 2 \times SSC at 65°C for 2.5 h. The filters were then treated with ribonuclease, washed and counted for 14 C and 32 P radioactivity²².

to Marmur²⁵. The DNA was further deproteinized by two consecutive treatments with pronase (0.2 mg/ml.) in SSC (0.15 M NaCl-0.015 M sodium citrate, pH 7.2) and by re-extraction with water saturated phenol. Traces of ribose oligonucleotides were removed by pelleting of the DNA overnight at 42,000 r.p.m., 20° C, in an MSE ultracentrifuge. The DNA was sheared by rapid stirring or by passage through a French Press at 6,000-20,000 pound/inch². The molecular weight of single stranded and native DNA was determined by the spill-over centrifugation technique as described in detail by Studier²⁶.

DNA was banded as described⁴. 5.2 g CsCl was mixed with 4 ml. 0.1×SSC containing sheared DNA together with DNA from *E. coli* labelled with ¹⁴C. The gradients were centrifuged to equilibrium in an MSE angle rotor²⁷ at 42,000 r.p.m., 25° C, for 36 h. Six-drop fractions were collected in 0.5 ml. 0.1×SSC. The absorbance at 260 nm was determined and each fraction of the gradient challenged with ³²P-labelled, chased rRNA as described earlier⁴ (see also legends to Figs. 2 and 4). The filters were washed according to the batch method⁴ and counted. Only machine background has been deducted from the measured radioactivity.

Note added in proof. Since submitting this article, we have learned from O. L. Miller (Oak Ridge) that when the *E. coli* genome is spread and examined in the electron microscope, he observed the scattered arrangement of the ribosomal DNA cistrons, in accordance with our conclusions for *Proteus* and *Serratia*.

Determination of Diffusion Coefficients of Haemocyanin at Low Concentration by Intensity Fluctuation Spectroscopy of Scattered Laser Light

by

R. FOORD
E. JAKEMAN
C. J. OLIVER
E. R. PIKE

Royal Radar Establishment, Malvern

R. J. BLAGROVE
E. WOOD
A. R. PEACOCKE

Nuffield Department of Clinical Biochemistry,
University of Oxford

Electronic analysis of optical signals, known as digital autocorrelation of clipped photon-counting fluctuations, has been used to measure diffusion coefficients of haemocyanin at concentrations ranging from 0.08 to 12.0 mg/ml. At 0.5 mg/ml., with laser power 30 mW, 1 per cent accuracy is achieved with a measurement time of only 30 s.

MEASUREMENTS of the diffusion coefficients of biological macromolecules in solution have sought chiefly to determine their molecular weights by applying the Svedberg equation, which relates these quantities to their sedimentation coefficient and partial specific volume. Until the early 1960s, this was the chief method for determining the molecular weights of proteins and, to a lesser extent, of polysaccharides¹⁻³. This led to the development of better methods for measuring diffusion coefficients^{4,5}. Accurate measurement of diffusion coefficients has always been difficult, however, because great care is needed in forming sharp, stable boundaries, because the optical components must be accurately aligned and because the measurements take a long time (from a few hours to days). This is a particular problem with materials of limited stability. Diffusion coefficients are frequently and readily determined by interference optical analysis of diffusing boundaries in a synthetic boundary cell in an ultracentrifuge, but their accuracy is seldom better than 5 per cent and, although stabilized, the diffusing boundary is inevitably disturbed in the rotating cell. Alternatively, the spreading of sedimenting boundaries may be used to determine diffusion coefficients, but the method is only accurate⁶ to

about 10 per cent, is complicated and is subject to limiting theoretical assumptions.

Because of these difficulties in measuring diffusion coefficients, sedimentation equilibrium methods are often preferred for molecular weight determinations, both because of their inherent accuracy and because of the great information that can be obtained from them. Most laboratories which have an ultracentrifuge, however, regularly submit their preparations of biological macromolecules to the quicker sedimentation velocity runs (if only for purely diagnostic purposes), and it would be a great help if an equally rapid and accurate method for measuring diffusion coefficients were also available. If diffusion coefficients could also be determined in a mixture of individual components which were identifiable as separate peaks in sedimentation-velocity runs, then estimates of their molecular weights could also be made without isolating them. We describe here a method for determining diffusion coefficients very accurately on small volumes at low concentrations by digital autocorrelation of scattered photons from a laser beam. Using this method, diffusion coefficients at various concentrations of haemocyanin from *Murex trunculus* have been determined.

Intensity Fluctuation Spectroscopy

Information about the distribution of relative velocities of pairs of particles taken from a set of randomly moving scatterers can be obtained from the spectrum of intensity fluctuations of scattered coherent radiation⁷. An excellent review is given by Atlas⁸. This technique was first used with coherent optical sources by Alpert *et al.*⁹ and by Ford and Benedek¹⁰.

A solution of macromolecules undergoing Brownian motion is just such a (Gaussian) source. The spectrum of scattered light can, in this case, be related to the diffusion coefficients which control the motion. Diffusion coefficients were first measured in this way in 1967 by Dubin, Lunacek and Benedek¹¹, although Cummins¹² made similar measurements in 1964 by a heterodyne technique. A third possibility has been demonstrated by Jakeman *et al.*¹³, who used statistical analysis of photon-counting distributions. The digital techniques used in this work can also be used directly to obtain the spectrum of scattered light. The information contained in the scattered light is, in this approach, retrieved from the train of points in time at which photodetection events take place at the detector. The probability of a photodetection is proportional to the intensity of the light, so that the fluctuations in intensity caused by beating together of the various Doppler-shifted frequencies are shown by bunching of the train at high intensities and thinning out at low intensities. The frequencies present in these intensity fluctuations are found by comparing the train with itself at a later time. The bunchings will match up one cycle later if a given frequency is present. This process of extracting spectral information is called digital autocorrelation.

Fig. 1. A schematic indication of the clipped photon number $n_q(t)$. The sampling time T is the period of the shift clock of Fig. 2.

Foord *et al.*¹⁴ have found that direct autocorrelation of photon counting functions in real time is potentially the most accurate method. Although a full digital autocorrelator could be constructed, it would be expensive, and a simpler technique would involve very little loss in statistical accuracy. This is based on a method, originally formulated for use in the microwave region, which makes use of the fact that the zero crossings of a Gaussian signal contain most of the spectral information. These are the points in time at which the signal amplitude passes zero. The analogue of this microwave technique for use in optical spectroscopy has been given by Jakeman and Pike¹⁵. The principle is as follows. We introduce the quantities, for integral q , illustrated in Fig. 1

$$\begin{aligned} n_q(r, t) &= 1 \text{ if } n(r, t) > q \\ &= 0 \text{ if } n(r, t) \leq q \end{aligned} \quad (1)$$

where $n(r, t)$ is the number of photodetections over a small area A at r in a short time interval T at t . A single-

channel-clipped, normalized, autocorrelation function $g_q^{(2)}(\tau)$ may then be defined as follows

$$g_q^{(2)}(\tau) = \frac{\langle n_q(r, t) n_q(r, t + \tau) \rangle}{\langle n_q \rangle^2} \quad (2)$$

where the angle brackets denote a long-time average. For stationary Gaussian light, this may be expressed¹⁴ in terms of the optical correlation function $g^{(1)}(\tau)$ (the Fourier transform of the optical spectrum) as

$$g_q^{(2)}(\tau) = 1 + \frac{1+q}{1+\langle n \rangle} |g^{(1)}(\tau)|^2 \quad (3)$$

It is clear that a measurement of $g_q^{(1)}(\tau)$ would give the required spectral information. Moreover, it can be determined much less expensively than the full autocorrelation function because it involves multiplication only by zeros or ones, and this can be accomplished by simple binary circuits.

In the case of light scattered from the uncorrelated Brownian motion of monodisperse macromolecules, which are small compared with the wavelength, the optical correlation function is given by

$$g^{(1)}(\tau) = e^{-K^2 D_T \tau} \quad (4)$$

where D_T is the translational diffusion coefficient and K is the scattering vector. This equation is the three-dimensional Fourier transform of the expression given by Chandrasekhar¹⁶ (eq. 172) for the real-space correlation function. In work of high accuracy, equation (3) has to be corrected for the fact that A and T have finite values. Thus, for scattering from Brownian motion, we obtain finally

$$g_q^{(2)}(\tau) = 1 + f(A, T, \langle n \rangle, q) \frac{1+q}{1+\langle n \rangle} e^{-2K^2 D_T \tau} \quad (5)$$

The experimental determination of this quantity will be discussed in the next section.

Experimental Determination of $g_q^{(2)}(\tau)$

A diagram of the single-clipped digital autocorrelator is given in Fig. 2. Photons detected by the photomultiplier (I.T.T. FW130) are amplified and then standardized in a discriminator to give a train of pulses corresponding to the intensity fluctuations of the light incident on the detector. This pulse train is then limited in one channel by a set-reset flip-flop which gives an output in a sample time only when more than q pulses arrive. The clipped signal is moved sequentially down a shift register by a clock which determines the sample time. It is then cross-correlated with the original digital signal by making the elements of the shift register control the input gates to separate channels of a 1 MHz accumulator (a bank of counters). For the work described here, the light intensity was sufficiently low for $q=0$ to be used so that the arrival of one or more photons in a sample time entered 1 into the shift register. The distribution obtained clearly has the form $\langle n_q(0)n_q(ST) \rangle / \langle n \rangle^2$ which is the required $g_q^{(2)}(\tau)$ described above at $\tau=ST$; S is an integer corresponding to the channel of the store and T is the sample period. $N^2 \langle n_q(0)n_q(ST) \rangle$ corresponds to the contents of channel S of the store, $N \langle n \rangle$ to the total unclipped counts and $N \langle n_q \rangle$ to the total clipped counts where N is the number of samples. All of these quantities are recorded in counters. The contents of the store are therefore normalized against the product of the total counts and the total clipped counts to obtain $g_q^{(2)}(ST)$. By plotting $g_q^{(2)}(ST) - 1$ on a logarithmic scale against the time ST , equation (5) shows that a straight line should be obtained with slope $-2D_T K^2$. A typical result is shown in Fig. 3. D_T is usually corrected to the value of diffusion constant at 20°C in water, $D_{20, w}$.

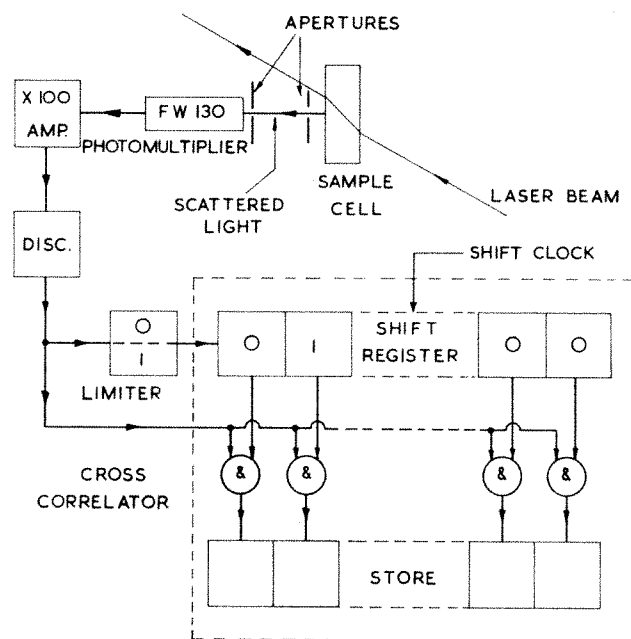

Fig. 2. A block diagram of the single-clipped digital autocorrelator.

The scattering vessels used for most of the work were spectrofluorimeter cells 2 cm \times 1 cm cross-section. Solutions and vessels were prepared by conventional techniques used in light-scattering studies. To reduce the effect of large impurities such as dust in the solution, the scattering was observed at an angle of 90°. The focused beam from a Spectra-Physics 125 He-Ne laser was scattered by the solution in the cells and a small solid angle of this light was defined by a two-aperture system. In this experiment, approximately 4 per cent of the coherence area and 10 per cent of the coherence time were used. This gives a value of 0.82 for $f(A, T)$ (unpublished results of E. Jakeman, C. J. Oliver and E. R. Pike). The system was aligned by a reference beam passing through both apertures to the photomultiplier and the light was reflected from the cell walls back along its own path. By ensuring that the light from the main laser beam incident on an adjacent face of the cell was also reflected normally, the two beams were known to be normal within the accuracy of the cell construction. It was necessary to achieve an

Fig. 3. A typical result for the autocorrelation function of haemocyanin. The concentration was 1.5 mg/ml. The diffusion coefficient $D_{20,w}$ was calculated to be $1.03 \pm 0.01 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ corresponding to an experimental time of 10 s.

angular accuracy of $\pm \frac{1}{2}^\circ$ for an overall accuracy of 1 per cent in D_T .

Applications of the Technique

One of the major disadvantages of earlier attempts¹¹ to determine diffusion coefficients of proteins in solution from line widths of a scattered laser beam was that high concentrations of the smaller globular proteins were required (scattering intensity is proportional to the square of molecular weight). We have therefore determined by the autocorrelation method the diffusion coefficients of two typical proteins in this lower molecular-weight range, bovine serum albumin (BSA; Armour Pharmaceutical Company) and lysozyme (BDH) at concentrations generally used in other hydrodynamic studies. Over the whole of the concentration range 0.5 to 20.0 mg/ml. the value of D_T for BSA in 0.1 M NaCl plus 0.01 M phosphate buffer (pH 6.0) at 20° was $5.70 (\pm 0.05) \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ giving a value of 5.76 ± 0.05 for $D_{20,w}$. With lysozyme in 0.1 M NaCl plus 0.01 M phosphate buffer (pH 6.0), there was a slightly greater scatter of points in the concentration range 3 to 20 mg/ml., giving a larger error in the value of $D_{20,w}$ which was $10.6 (\pm 0.2) \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$. Even with the most dilute solution of lysozyme (3 mg/ml.), an accuracy of ± 4 per cent was achieved in 2 h. Haemocyanin was obtained from specimens of the whelk *Murex trunculus* collected off the shores of Malta. Concentrations were determined from the absorption at 280 nm of solutions in 0.05 M borate buffer (pH 9.2) plus 0.01 M EDTA. At this pH the contribution of light scattering was greatly reduced¹⁷ and the extinction coefficient was $1.39 \text{ mg}^{-1} \text{ ml. cm}^{-1}$. The diffusion coefficient of *M. trunculus* haemocyanin has been measured over a wide range of concentrations in 0.1 M NaCl, 0.1 M acetate buffer (pH 5.7). In the concentration range 0.08 to 5.0 mg/ml., $D_{20,w}$ was $1.03 (\pm 0.01) \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$, rising to $1.08 (\pm 0.01) \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ at 12 mg/ml. (Fig. 4). No deviation from a single Lorentzian distribution was detected in the range of angles 30° to 90°. The value obtained compares favourably with that of Lontie (unpublished results), namely $1.1 (\pm 0.05) \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ at 11.5 mg/ml., measured on a Zeiss diffusion interferometer. Combination of our diffusion coefficient with the sedimentation coefficient for *M. trunculus* haemocyanin gives a molecular weight of $9.2 (\pm 0.1) \times 10^6$.

To show that the method is not limited by solvent, D_T for haemocyanin has been measured in 5 M guanidinium hydrochloride containing 0.5 M 2-mercaptoethanol. From the scattered intensity it was obvious that although the molecular weight was considerably reduced, it was still relatively high. Combination of D_T with the sedimentation coefficient gave a molecular weight of 210,000 ($\pm 20,000$), which suggests disruption into fortieths. This has been confirmed by conventional light scattering measurements. The only additional information required when working at high salt concentrations or in organic solvents is the refractive index of the medium.

It was possible to measure D_T for haemocyanin on only 15 $\mu\text{l.}$ of solution. The cell was a piece of capillary tubing of 1 mm internal radius and 0.5 cm long. At the concentration used, only 30 s of machine time were required to measure D_T to an accuracy of ± 1 per cent. Even at the lowest concentration used, 0.08 mg/ml., D_T could be determined to ± 1 per cent in three minutes. The statistical accuracy is roughly proportional to the inverse of the concentration and the square root of the total time of

Table 1. COMPUTED EXPERIMENTAL TIMES NEEDED AT DIFFERENT CONCENTRATIONS OF HAEMOCYANIN TO OBTAIN (a) 1 PER CENT AND (b) 0.1 PER CENT STATISTICAL ACCURACY IN D_T

Conc. mg/ml.	Mean number of photons per sample	(a) min	(b) min
0.08	0.017	3	300
0.13	0.028	1.5	150
0.47	0.1	0.5	50
1.5	0.3	0.17	17

Fig. 4. The concentration dependence of $D_{20,w}$ for haemocyanin.

the experiment. Examples of computed experimental times required to attain statistical accuracies of 1 per cent and 0.1 per cent in D_T are given, for various concentrations, in Table 1. These agree with experimental results.

An interesting innovation made possible by this technique is the study of diffusion in mixtures of macromolecules. A preliminary study has been made on the apparently non-interacting mixture at pH 7 of bovine α -crystallin and haemocyanin in a weight concentration ratio of 10:1 to equalize the relative scattering powers. Although fitting the statistics to a sum of exponentials requires greater accuracy and longer experimental times (if a fit is forced to a single exponential, the result will approximate a weight average diffusion coefficient), the results were encouraging. Without any restraints at all in the fitting procedure, the D_T values were close to those observed for the separate components, although the relative proportions, as judged by the respective intensities, varied over a wider range. When the components interact, apart from the possible kinetic information available^{18,19}, the results should be useful both in detecting the presence of high molecular weight species and perhaps in estimating their size. This would help in the interpretation of other experiments on such systems. In a related

experiment, we have examined a solution of haemocyanin at an alkaline pH, where it is almost completely dissociated. The diffusion coefficients confirmed this and showed that the mixture contains mostly molecules of one twentieth and one half the original molecular weight.

The method reported here for measuring diffusion coefficients has several important advantages. There is no need to establish a concentration gradient, nor is stringent temperature control necessary to maintain such a gradient. The diffusion coefficient can be determined very accurately because the process is automatically a signal-averaging method. Furthermore, its measurement is relatively quick and the calculations are straightforward because of the digital output. The method is valid for any of the solvents used in macromolecular studies, is completely non-destructive, and only requires small volumes of solution. The concentrations needed are quite low and are similar to those needed for other hydrodynamic studies.

We should like to acknowledge useful discussions and assistance from Dr Walter Gratzer of King's College, London, and financial support from the MRC (A. R. P.), the Marquis Sciucina Trust Fund, Royal University of Malta (E. W.) and from CSIRO in the form of a post-doctoral studentship (R. J. B.).

Presence of EB Virus Nucleic Acid Homology in a "Virus-free" Line of Burkitt Tumour Cells

by

HARALD ZUR HAUSEN
HEINRICH SCHULTE-HOLTHAUSEN

Institut für Virologie der Universität Würzburg,
Luitpoldkrankenhaus,
8700 Würzburg

The presence of virus in Burkitt lymphoma cells is hard to confirm, but small amounts of viral DNA have now been revealed by hybridization with DNA from cells of the Raji line of the tumour.

THE viral aetiology of Burkitt's lymphoma has been suggested ever since its first description^{1,2}. The discovery of a herpes-type virus (EB virus) by Epstein *et al.*³ in tissue culture cells derived from these tumours, as well as the presence of high antibody titres against this agent in Burkitt lymphoma patients^{4,5}, supported the original hypothesis. In recent years considerable immunological evidence has accumulated which points to an interaction between EB virus and Burkitt tumour cells⁶⁻¹¹, and the

relationship of EB virus to another lympho-proliferative disorder, infectious mononucleosis, has been demonstrated^{12,13}. Nevertheless, the role of EB virus in the aetiology of any human malignancy is far from being established.

Recently, it became feasible to isolate DNA from partially purified EB virus^{14,15}, making it possible to determine whether or not viral nucleic acids are present in tumour cells. In addition, one can now decide whether

Fig. 1. Sucrose velocity sedimentation of EB virus ^3H -DNA, isolated from virus concentrates without deoxyribonuclease treatment before extraction. The virus concentrate (0.3 ml.) was layered on top of a sucrose gradient (20–35 per cent) in a buffer solution containing (per 100 ml.): 86.5 ml. reticulocyte standard buffer (RSB)²⁵, 10 ml. 0.1 M EDTA (pH 7.5), 2.5 ml. 4 M NaCl, and 1 ml. 5 per cent SDS. A solution consisting of 0.25 ml. 5 per cent SDS, 0.15 ml. 0.1 M EDTA, 0.15 ml. pronase P (Serva-Chemie, Heidelberg) (10 mg/ml.), 0.55 ml. RSB, and 0.1 ml. of non-labelled P3HR-1 RNA (about 400 μg), was added to the gradient. The tubes were incubated for 30 min at 37° C and then centrifuged in the 'SW 25-1' rotor of the Spinco preparative centrifuge for 18 h at 70,000g at 25° C. The fractions were collected from the bottom and examined for absorbance at 260 nm, for radioactivity, and for sucrose concentration. The sedimentation coefficient was determined according to Martin and Ames²⁶ by using 28S and 18S ribosomal RNA of P3HR-1 cells as markers.

Koch's first postulate, which requires the presence of the inducing agent in lesions of a disease, is true for the EB virus Burkitt tumour system.

We describe here a system which tests for the presence of EB virus DNA in tumour cells. The experiments were carried out with the assumption that EB genomes persist in every tumour cell like other well known DNA tumour viruses. To test this, the homology between the DNA from purified EB virus and nucleic acid derived from Burkitt tumour cells was studied. The results demonstrate that a "virus-free" line of Burkitt tumour cells contains approximately six EB virus genome equivalents per cell, as well as virus-specific messenger RNA.

Test System

A non-virus-producing line, Raji, isolated from a Burkitt lymphoma, was chosen. This line was established by Pulvertaft¹⁶. The cells were repeatedly reported to be EB virus negative by immunofluorescence and electron microscopy^{6,17,18}. Before use they were again tested for EB virus specific immunofluorescence and also subjected to virus-concentration procedures after prolonged labelling with ^3H -thymidine¹⁵. Both procedures failed to indicate the presence of EB virus. Raji cells, as well as all other cells used, were examined for mycoplasma contamination and found to be negative. Nucleic acids from P3HR-1 cells served as positive controls. These cells were derived from the P3J line of Burkitt tumour origin by cloning¹⁹. Approximately 10 per cent were repeatedly found to be EB virus positive by indirect immunofluorescence. Nucleic acid from Nil-2 cells, a line of Syrian hamster origin²⁰, served as a negative control. Nucleic acid from human KB cells was included in all tests. The maintenance of the various lines has been reported previously^{21,22}. Some experiments were carried out with DNA from cells of the HeLa line, the human leukaemia lines RPMI 64-10 (ref. 23) and SK-L1 (ref. 24), primary human leucocytes, and from *Micrococcus lysodeikticus*. Biopsy material obtained from a Burkitt lymphoma (kindly

supplied by Dr George Klein, Stockholm) was also examined.

The method for extraction of cellular DNA has been described²⁵. The technique of Warner *et al.*²⁶ was used for isolating total cellular RNA. The isolation and concentration of EB virus particles from P3HR-1 cells, as well as the isolation of viral DNA by equilibrium centrifugation in CsCl , have been described in detail¹⁵. Alternatively, DNA was extracted from virus concentrates by treating the preparations on top of sucrose gradients with sodium dodecyl sulphate (SDS) and pronase P. They were subjected to sedimentation as described in the legend to Fig. 1. DNA-DNA hybridization tests were performed according to Aloni *et al.*²⁷, with minor modifications²⁵. On filtration of 100 μg of radioactive heat-denatured cellular DNA through Schleicher and Schuell membrane filters, about 80 per cent of the DNA was retained by the filters. The procedure of Fujinaga and Green²⁸ was used for DNA-RNA hybridizations.

Compared with other common human DNA viruses (for example, herpes simplex, adenovirus, vaccinia), the yield of viral DNA per cell was very low (approximately 2 μg from 4×10^9 P3HR-1 cells). This was the limiting factor in the design of our experiments. The specific radioactivities of the various ^3H -labelled viral DNA preparations varied between 19,000 and 22,500 c.p.m./ μg DNA.

Hybridization of Viral DNA with Cellular DNA

^3H -labelled EB virus DNA, obtained from partially purified and deoxyribonuclease-treated preparations and isolated by equilibrium centrifugation in CsCl ¹⁵, was used for initial hybridization experiments. The results of four tests are combined in Table 1. DNA derived from Raji cells and Burkitt tumour biopsy material annealed about twice as many counts as human DNA of non-Burkitt origin. The high background annealing of human cellular DNA with EB virus DNA, however, indicated the presence of contaminating cellular DNA in the viral DNA preparation. Further hybridization tests were therefore performed with viral DNA obtained by sucrose velocity sedimentation as described in Fig. 1. Two peaks of ^3H -labelled material were identified (Fig. 1). Most of the radioactivity sedimented at 44S; a smaller fraction at approximately 9S. Treatment of the partially purified virus preparation with deoxyribonuclease reduced the 9S peak but did not eliminate it. The same 9S material was recovered from tissue culture medium after virus had been removed by centrifugation.

Table 1. HYBRIDIZATION EFFICIENCIES OF EB VIRUS ^3H -DNA WITH DNA DERIVED FROM HUMAN AND HAMSTER CELLS

Cellular DNA from	No. of experiments	No. of filters tested	Percentage of input c.p.m. hybridized (range)
<i>M. lysodeikticus</i>	1	1	0.22
Nil-2	4	4	0.19 (0.14–0.26)
KB	4	6	0.54 (0.44–0.68)
HeLa	1	1	0.33
Primary leucocytes	3	3	0.63 (0.50–0.85)
RPMI 64-10	2	2	0.66 (0.53–0.79)
SK-L1	2	2	0.50 (0.36–0.64)
Raji	4	8	1.19 (0.78–1.68)
Burkitt biopsy W. N.	2	2	1.53 (1.38–1.68)
P3HR-1	4	4	10.22 (8.95–13.02)

Cellular DNA (100 μg per filter) was annealed with 10,000 (two experiments), 20,000 (one experiment), or 25,000 (one experiment) c.p.m. of EB virus ^3H -DNA, isolated by CsCl equilibrium centrifugation.

Table 2. HYBRIDIZATION OF 44S EB VIRUS ^3H -DNA WITH DNA FROM HUMAN AND HAMSTER CELLS

Cellular DNA from	C.p.m. hybridized	Percentage of input c.p.m. hybridized
Nil-2	22	0.22
Nil-2, infected with herpes simplex virus	26	0.26
KB	26	0.26
Raji	106	1.06

Cellular DNA (100 $\mu\text{g}/\text{filter}$) was annealed with 10,000 c.p.m. of EB virus ^3H -DNA, isolated by sucrose velocity sedimentation.

The 44S DNA was collected, dialysed and concentrated by evaporation. It was then used for hybridization with Raji, KB and Nil-2 DNA. In addition, a membrane filter containing DNA from Nil-2 cells, infected with 1 p.f.u./cell of herpes simplex virus and extracted 24 h after infection, was included in the test (Table 2). EB virus DNA, isolated by velocity sedimentation, gave no increased background annealing with human cellular DNA as compared with DNA from hamster cells. Infection of Nil-2 cells with herpes simplex virus for 24 h (almost every cell revealed cytopathogenic changes at this time) did not increase their capacity to anneal with EB virus DNA. DNA from Raji cells, however, hybridized with approximately four times as many counts. Thus the viral DNA preparations were free of detectable contamination with cellular DNA; moreover, there is no significant cross-hybridization between DNA from EB and herpes simplex viruses.

The 44S DNA was used to study its saturation level with Raji DNA (Fig. 2). DNA from KB and Nil-2 cells bound between 40 and 50 counts at an input of 10,000 c.p.m. DNA from P3HR-1 cells annealed with approximately 13 per cent of the input while Raji DNA bound 216 c.p.m. of a comparable input. At higher inputs a plateau was reached between 250 and 350 c.p.m. Thus Raji DNA was saturated with EB DNA at inputs between 10,000 and 20,000 c.p.m. By subtracting the background of KB and hamster DNA, about 200 c.p.m. of EB virus DNA annealed specifically with Raji DNA. The specific activity of the labelled viral DNA used in this experiment was 22,500 c.p.m./ μg , so that the 80 μg of cellular DNA bound to the membrane included about 0.009 μg of non-labelled viral DNA. The DNA content of a diploid human cell (Raji cells, used in these experiments, contain 47 and

48 chromosomes) is approximately 6×10^{-12} g (ref. 31). The weight of EB virus DNA should be identical to that reported for herpes simplex DNA (1.2×10^{-16} g) (ref. 32), for both sediment at 44S (ref. 33). These data permit a calculation of the number of EB genome equivalents per Raji cell: on this basis, Raji cells would contain on average six EB virus DNA equivalents per cell.

Hybridization of Viral DNA with Cellular RNA

The presence of DNA sequences in Raji cells which are homologous to EB virus DNA raised the question whether or not they are transcribed. This was studied by annealing cellular RNA with non-labelled viral DNA. The isolation of unlabelled viral DNA was more difficult to achieve than the purification of radioactive EB virus nucleic acid. Because of the low concentration of viral material, most of the purification steps had to be done "blindly"; only low yields of viral DNA have therefore been obtained and no saturation or competition experiments have been carried out. The viral DNA was only purified by equilibrium centrifugation in CsCl .

Table 3. HYBRIDIZATION OF NON-LABELLED EB-VIRUS DNA WITH CELLULAR ^3H -RNA

RNA from	C.p.m. hybridized with EB virus DNA ($\mu\text{g}/\text{filter}$)	
	0.2	1.1
Nil-2	3	57
KB	9	82
Raji	42	191
P3HR-1	58	236

EB virus DNA (0.2 or 1.1 μg per membrane) was annealed with 400,000 c.p.m. of cellular ^3H -RNA. The specific activities (c.p.m./ μg) for RNA derived from Nil-2, KB, Raji, and P3HR-1 cells were 28,300, 47,400, 46,600 and 9,550, respectively. Each filter containing EB virus DNA was controlled by an additional membrane treated with corresponding amounts of purified adenovirus type 4 DNA and annealed with equal counts of cellular ^3H -RNA. The hybridized counts in the table represent the additional radioactivity annealed with EB virus DNA as compared with the corresponding membrane containing adenovirus DNA.

The results of two preliminary experiments are combined in Table 3, and show that EB virus DNA hybridizes with Raji RNA and RNA from P3HR-1 cells to a similar degree. This should be the result of the low specific activity of the P3HR-1 ^3H -RNA preparation used, which was approximately five-fold lower than that of the Raji cells. The hybridization of ^3H -RNA derived from KB cells was close to the background level of Nil-2 ^3H -RNA. It does therefore seem that Raji cells synthesize an EB virus specific RNA, although additional experiments are needed to characterize this RNA and determine the extent of its transcription.

Our demonstration of the persistence of EB virus DNA, or parts thereof, in tumour cells serves to indicate that the EB virus has features characteristic of known DNA tumour viruses, although the state of the viral nucleic acids within the cell, and their biological significance, remain to be clarified. The feasibility of demonstrating the presence of EB virus nucleic acid in "virus-free" cells should provide an additional tool for studying the role of this virus in the induction of human malignancies.

We thank Drs Eberhard Wecker (Würzburg), Werner Henle (Philadelphia), and George Klein (Stockholm) for discussion and suggestions; and Mrs Sharon Hermen for assistance. This work was supported by the Deutsche Forschungsgemeinschaft, Bad Godesberg.

Genetic Analysis with Man-Mouse Somatic Cell Hybrids

Evidence of an active linkage between the human genes that control lactate dehydrogenase B and peptidase B is presented. It is also concluded that there is no link between the genes for lactate dehydrogenase A and lactate dehydrogenase B.

Linkage between Human Lactate Dehydrogenase B and Peptidase B Genes

By a genetic analysis of a series of enzyme markers in human-mouse somatic cell hybrids, we conclude that the human genes controlling lactate dehydrogenase B (LDH B) and peptidase B (Pep B) activities are linked.

Nine hybrid lines, each presumably originating from a different heterokaryon, were derived from a cross between 1-T, a subclone of a bromodeoxyuridine resistant, thymidine kinase deficient subline of the mouse cell line 3T3¹ (kindly provided by Dr H. Green) and peripheral white blood cells from a normal human female (for methods, see ref. 2). Eight of the nine hybrid lines are clones derived from a population of hybrid cells comprising several hundred original hybrid colonies. They were isolated about 30 days after fusion, and then grown as mass cultures. Line 3-31-Z resulted from a fusion of 1-T with white blood cells, which had been stored in liquid nitrogen³. It was chosen as an original hybrid colony. With some exceptions, all enzyme assays of the lines were carried out on the same batches of cells harvested at 75 to 120 days of culture after fusion. The cells were stored as washed pellets in Beckman tubes in liquid nitrogen and extracted by freeze-thawing in H₂O (50 μ l./2 \times 10⁶ cells) immediately before use.

Markers

The zymogram technique⁴⁻⁷ provides a particularly convenient and useful set of markers because it identifies primary gene products whose species of origin can usually be distinguished. Allelic variants are also, in general, codominantly expressed. The enzymes we have investigated are LDH A and LDH B (Fig. 1), Pep A, B, C and D (Fig. 2), supernatant NAD-dependent malate dehydrogenase (MDH), phosphoglucosmutase (human PGM₁ and PGM₂, see refs. 8 and 9), glucose-6-phosphate dehydrogenase (G6PD X-linked form), deaminase (ADA, ref. 10) the indophenol oxidase isozyme found in haemolysates (IPO, ref. 11) and phosphohexose isomerase (PHI, ref. 12).

The number of subunits in an autosomally inherited enzyme can be predicted from the number of intermediate bands in zymograms from heterozygotes for structural variants. In every case reported^{4-7,13} the number of intermediate bands, which represent interspecific heteropolymers in somatic cell hybrids displaying both human and mouse activity, corresponds to the number found in heterozygotes^{8-12,14-18}. Thus, we have found that MDH, IPO, Pep A and D and PHI can form one heteropolymeric band with intermediate mobility which is not observed, or occurs only as a trace, in extracts from cell

mixtures. Judging from the relative activities of the various bands, assembly of subunits usually seems to be random. PGM₁ and PGM₂, ADA and Pep B do not form heteropolymeric bands either in heterozygotes or in hybrids.

Table 1 gives the distribution of human enzyme activities in the nine hybrid lines. Where possible, a crude estimate of the relative amount of human, relative to mouse, enzymatic activity has been given. The contribution of the human form to the total activity is in general less than, and in no case appreciably greater than, that of the murine molecules. The simplest explanations for this observation are that whereas the heteroploid mouse parent line probably contains at least two copies of most genes, extensive human chromosome losses have eliminated, in most cases, at least one of a pair of homologues, and that within a hybrid cell line there may be considerable population heterogeneity with regard to human gene content. The second explanation is supported by a comparison between G6PD patterns from hybrids in which the X-chromosome is selectively maintained⁴ and patterns from other lines⁴, and by the correlation between the amount of human enzyme activity in a line and the

Fig. 1. LDH zymograms of hybrids and parental cells. Acrylamide gel electrophoresis was carried out⁴ on 5 μ l. of extract per sample. BREN fibroblasts are derived from the human donor in the cross; 1-T are cells in the mouse parent line. Hybrid 1 (HY1) shows the presence of human A subunits, hybrid 2 (HY2) has human A subunits and displays (compared with the mouse parent 1-T) an increase in LDH-B activity, probably because of the human LDH-B gene; hybrid 3 (HY3) shows only presumed human B activity.

Quantitative variations of activity are neglected.

proportion of clones derived from it, which contains this marker (compare Tables 1, 2 and 3).

Although no precise quantitative evaluation of the zymograms was made, it was clear that the levels of human and mouse enzyme activities were not closely correlated. Our previous data⁸ showed that high levels of human G6PD were conserved in hybrids derived from a cross with a hypoxanthine-guanine phosphoribosyl transferase deficient mouse line. None of the hybrids described here, derived from a cross between a thymidine kinase deficient cell line and white blood cells of a female with an A+B+G6PD phenotype, showed any detectable amounts of human G6PD.

In Table 1, it is assumed that the increased LDH B activity found in many hybrids is of human origin, although this cannot be demonstrated by electrophoresis. Patterns with increased B-subunit activity were previously only observed with human A subunit admixture⁸. The occurrence of this pattern among the hybrids described here (Fig. 1) argues against the possibility that some sort of regulatory effect related to the presence of human LDH A activity is responsible for an increase in the production of mouse B subunits.

Linkage Analysis

The distribution of human enzyme activities suggests close association between two pairs of human markers: the data from the lines indicate a linkage between LDH B and Pep B activities and between MDH and ADA activities.

These possibilities have been further investigated by a clonal analysis of the lines that carried these markers. Subclones were isolated at 55 to 75 days of culture after fusion. They were harvested about 40 to 50 days after isolation and assayed for the presence of human enzymes which could be detected in the line from which the clones were derived. The results of this analysis (Tables 2 and 3) confirm the association between LDH B and human Pep B activities found in the lines, and so indicate a linkage between the structural loci coding for LDH B and Pep B

in man. The possibility that the linkage involves regulatory rather than structural genes is, however, not ruled out. In particular it is conceivable that the structural Pep B locus is linked to a gene the presence of which leads to an increase in mouse LDH B activity in the hybrids and may also be necessary for human LDH B expression. Genetic regulation of LDH B activity has been demonstrated in mouse erythrocytes²⁰. The data given by Ruddle *et al.*²¹ in the accompanying paper make such an explanation extremely unlikely, however.

The complementary case of linkage between a gene regulating human Pep B activity and the structural LDH B locus would be expected to give rise to a situation in which human Pep B activity is only, but not always, there when human LDH B is present—a situation analogous to that found for MDH and ADA (see below). Strong selective forces may also lead to a complete coupling of the loss or maintenance of two human chromosomes carrying respectively the LDH B and Pep B genes.

The results obtained by Ruddle *et al.*²¹ from a cross involving a donor carrying an electrophoretic LDH B variant argue strongly against the involvement of a gene which regulates mouse LDH B activity. The clonal analysis of lines 4-12-Z and 4-42-Z argues against close linkage between the human structural genes coding for MDH and ADA. The data obtained from 4-12-Z are not very informative, as this line seems to be relatively uniform genetically and does not segregate for a number of the human markers. Whereas human MDH is present in

Table 3. DISTRIBUTION OF LDH-B AND PEP B ACTIVITY AMONG THE CLONAL OFFSPRING OF VARIOUS LINES

LDH B/Pep B* line	4-11-Z	4-12-Z	4-31-Z	4-45-Z	Total
+	7	13	6	0	26
±	1	0	1	1	3
-	2	0	2	7	11

* Complete linkage of human Pep B and increased LDH B activity, presumably because of the presence of human LDH B subunits, was observed. A rough quantitative evaluation of the zymograms suggests close correspondence of the activity levels of the two enzymes in the different cell populations. The frequency of the ++ clones suggests that their modal genotype contains one copy of the presumed LDH B/Pep B chromosome.

Fig. 2. Zymograms of peptidases of 1-T, the mouse parental line; BREN, fibroblasts derived from the human donor of the white blood cells for the cross and hybrid cell populations. 10 μ l. of extract was used for each sample. Starch gel electrophoresis and staining techniques were according to ref. 16. (A) Pep A: valyl-leucine was used as substrate. The slower band in the human fibroblast (BREN) is not found in haemolysates from the same person. We call mouse Pep A (M-Pep A) the only band observed in 1-T that forms hybrid molecules (H-M-Pep A) with human Pep A (H-Pep a) in the hybrids (HY). (B) Pep B; leucyl-glycyl-glycine was used as substrate. We designate as mouse Pep B (M-Pep B) the only band with substantial activity appearing with this substrate in mouse cell extracts. As in the case of the human Pep B activity, it is not seen with the substrates used to stain for Pep A, C and D. Hybrids show both a human and a mouse band. (C) Pep C: the substrate used, leucyl-alanine, can be hydrolysed by Pep C (H-Pep C) as well as Pep A (H-Pep A) in human haemolysates. In the mouse parent (1-T) a more anodic band appears in addition to the one designated as Pep A (M-Pep A). The patterns in haemolysates of the human white cell donor correspond to a normal Pep C 1 phenotype¹⁸. Fibroblast extracts of the same donor give a different pattern: in addition to the strongest band corresponding to the main Pep C zone in haemolysates, a faster migrating band, also found in HeLa cell extracts, is observed. These two bands were present in hybrids scored positive for human Pep C. In the fibroblast extracts a further slower moving band, not found in HeLa cell extracts, is seen. As it migrates at the same position as M-Pep A it could not be detected in hybrids. (D) Pep D: substrate was leucyl-proline. The human donor (BREN) displays a heterozygous phenotype, probably Pep D²-1 (ref. 17). In two hybrids, in addition to the only band hydrolysing this substrate in 1-T extracts, another band is found. The different positions of these bands suggest that only one human Pep D allele is present in each hybrid, namely Pep D¹ in HY1 and Pep D² in HY2 (see Table 1). These bands would represent molecular hybrids between the mouse enzyme and the respective human Pep D protein. Our interpretation of the peptidase patterns in mouse cells agrees with recent results obtained by Lewis and Treslove¹⁹.

all twelve clones derived from 4-42-Z, however, only five of them exhibit human ADA activity. Thus, wherever ADA is found, MDH is also present but the reverse is not necessarily true. If this association is confirmed, one of the following explanations seems most likely: the structural genes for MDH and ADA are linked in man but either (1) in line 4-42-Z an early translocation or deletion event produced a population component in which this linkage was disrupted and the human ADA gene was lost; or (2) in some 4-42-Z subclones human ADA activity is not expressed, because another human gene, not linked to MDH but necessary for ADA expression, is missing; (3) the complementary case to (2), namely linkage of such a "regulator" gene, but not the structural ADA locus, to the MDH gene would be expected to give the same result. Recent results²², which have indicated that in prokaryotes the level of species specificity of certain parts of the protein synthesizing machinery seems to be different for different genes, are of some interest in this context. Finally, an association between MDH and ADA could be the result of some form of interaction between the chromosomes carrying these markers which gives a selective advantage to hybrids that contain both elements.

Evolution of Hybrid Lines

We have previously suggested that hybrid lines quite rapidly reach a relatively stable equilibrium with respect to their content of human chromosomes⁶, and also that the evolution of the hybrids following cell fusion may be affected by quite strong selective pressures. Our new data further support these theories.

The LDH and IPO activities of the nine hybrid lines described here were assayed twice within a period of about 20 days, namely at about 80 and 100 days of culture after fusion. Two substantial changes indicating selective effects were observed. One line, 4-45-Z, showed a considerable increase in LDH B activity, whereas another line, 4-43-Z, lost its previously observed human IPO activity. (Cells for subclone isolation from 4-45-Z were plated out at the time at which the earlier assay was carried out.) In each case, the pattern observed in the first sampling did not correspond to that expected from random assembly of subunits and thus indicated population heterogeneity with respect to these genes.

The mean number of human enzyme activities detected per line was 4.6 (counting LDH B and Pep B as one) with

a variance of 10.5. This is not a Poisson distribution, and it indicates that the overall probability of retention of human chromosomes varies from line to line. There is, in addition, significant heterogeneity between the various enzymes with respect to the proportion of lines which have the respective activities. This suggests that some chromosomes may have a higher overall probability of being retained in the hybrids than others—a suggestion which has also been supported by preliminary karyotypic analysis (unpublished results of M. N.). There are also significant differences between the lines with respect to the proportion of clones which showed enzyme activity. The fate of a given chromosome may thus vary from line to line.

Clonal analysis of the various lines clearly demonstrates their individuality (see Table 2). Line 4-12-Z displays little or no segregation for five human enzyme activities which segregate frequently in other lines. For the other four enzymes present in 4-12-Z, however, considerable genetic variation apparently still existed at the time the subclones were isolated. Our previous results⁸ suggest that within a line stable segregating polymorphisms can exist—the fact that a gene segregates in subclones of a line does not necessarily mean that it will subsequently be lost from the population of cells that constitute the line.

If the very rapid early chromosome losses are caused by mechanisms different from the postulated selective pressures that seem to prevail later in the evolution of a line, then the curious fact that an enzyme, MDH, which was found in only two of the lines is so stably transmitted to their clonal offspring could be more than coincidental. Certain chromosomes that may initially be lost more rapidly than others may be expected to be found only in lines where they are maintained by relatively strong selective pressures.

Another important feature of the evolution of hybrid cell populations is the occurrence of associations between different human markers among subclones of one or more lines, which are not observed among the lines or among the clonal offspring of other lines. Data on PGM₂ and IPO which illustrate such pairwise patterns of association are shown in Table 4. There is no association among the lines, while the clones derived from 4-11-Z and 4-12-Z show some association. In the case of 4-12-Z, this simply reflects its tendency to retain more human chromosomes. Specific associations between pairs of chromosomes in clones from a given line could be caused by selective interactions between chromosomes. Marin (personal communication) has also suggested that they could arise from the elimination of associated sets of chromosomes during early mitoses following cell fusion. As already mentioned, such associations, whatever their origin, could lead in some cases to spurious apparent genetic linkages. Thus it is important to analyse clones derived from several lines when suspected linkages between unselected markers are to be tested. Further evidence concerning these possibilities emerges from karyotypic analysis of these hybrids (Razavi *et al.*, in preparation). This analysis is complicated by the relatively high level of karyotypic instability in heteroploid cell populations and in particular by the fact that bi-armed human-like chromosomes may be generated in the parent mouse cell line and in the hybrid lines derived from it. Thus, in some of the hybrid lines novel chromosomes were found that could be assigned neither to the normal human nor to the karyotype of the mouse parent line.

Our data seem to confirm the validity of an experimental design in which a relatively large number of independently isolated hybrid lines is screened as soon as possible after fusion for a panel of genetic markers. Significant associations can subsequently be tested by one or more subclonings from several lines. It is to be expected that other linkages will soon be established in this way. The next phase of this approach to somatic

Table 4. JOINT SEGREGATION OF PGM₂ AND IPO ACTIVITIES IN CLONES AND LINES

Linkage between Human Lactate Dehydrogenase A and B and Peptidase B

METHODS for establishing human gene linkage relationships, using somatic cell hybrids between man and mouse, have recently been developed^{1,2}. They are based on electrophoretic differences between homologous enzymes, on differences between chromosomes, and on the predominant diminution of only human chromosomes from the hybrids. The characterization of enzyme phenotypes in clonally derived cell populations containing different numbers and combinations of human chromosomes can be used to infer human gene/gene and gene/chromosome linkage relationships.

It has been suggested, on the basis of clonal differences in the activity of total LDH B, that the genes coding

for the A and B subunits of lactate dehydrogenase (LDH) are unlinked^{3,4}. Because the electrophoretic mobilities of the mouse and human B subunits are identical, the conclusion was only tentative, however, and other possibilities exist. For example, LDH A and LDH B structural genes may be linked, but other unlinked gene(s) may modulate the synthetic rate of mouse and human LDH B subunits. This suggestion is supported by genetic evidence for genes which control the expression of LDH B in mouse erythrocyte⁵.

We argued that the problem might be resolved using either a mouse or human structural variant of the LDH B subunit, and describe here a human LDH B variant, LDH B (var), and its segregation in clonal populations of mouse/human hybrids. This provides strong evidence for the absence of linkage between human LDH A and LDH B genes. Besides scoring the LDH phenotypes, we have ascertained the expressions of a total of fifteen different human enzyme phenotypes in a total of twenty-six clones and sixty-six subclones. These data suggest that the human genes for LDH B and peptidase B (Pep B) are linked, and this is supported by the accompanying report of Santachiara *et al.*⁶. Moreover, negative linkage of many other genes can be inferred.

Somatic Cell Hybrids and Clones

Peripheral leucocytes were collected from the proposita, J, and her mother, C. The leucocytes were separated from defibrinated whole blood by dextran sedimentation⁷, and then hybridized to mouse RAG cells using β -propionolactone-inactivated Sendai virus^{8,9}. The parental cells were mixed at a ratio of 1:1 at a total density of 4.0×10^6 per ml. in suspension with 1,000 h.a.u. of Sendai virus. The hybrids were selected in Dulbecco-Vogt modified Eagle's medium¹⁰ with 10 per cent newborn calf serum lacking γ -globulin and supplemented with hypoxanthine (10^{-4} M), aminopterin (4×10^{-7} M), and thymidine (1.6×10^{-5} M) (HAT medium¹¹). The RAG parent is sensitive to this medium because it lacks hypoxanthine-guanine phosphoribosyl transferase (HG-PRT) activity⁸. Leucocytes do not proliferate *in vitro*. The hybrids proliferate in HAT because suppression of proliferation is recessive, and the HG-PRT deficiency in RAG is complemented by the unimpaired human HG-PRT gene. The selection system has been described in detail elsewhere^{2,8,9,11}. The mouse RAG cell line was derived from a renal adenocarcinoma of a BALB/c mouse. It is particularly appropriate for hybridization because of its relatively unmodified karyotype⁹.

Two independent series of hybrids were produced, and termed C and J after the respective human donors (Fig. 1). Mass cultures of C and J hybrids were recovered one month after hybridization. These possessed very weak activity for human LDH A and LDH B (var) phenotypes, indicating that only a few cells in the mass heterogeneous populations carried the LDH A and B (var) genes. The C and J populations were cloned to give the C and J series of independently derived clones. The LDH phenotypes of these clones were then examined to isolate hybrids possessing the LDH B (var) phenotype. Derivative subclones were produced from clones in the J series as shown in Fig. 1.

Linkage Relationships of LDH A and LDH B Genes

Previous studies have shown that lactate dehydrogenase is a tetramer¹². Two separate and distinct gene loci, termed A and B, code for subunit polypeptides which are distinct in their amino-acid composition¹³. The A and B loci are generally expressed in most somatic cell types, but in differing activity ratios¹⁴. The a and b subunits interact to give rise to five molecular forms of the tetrameric enzyme, namely, a_4 , a_3b , a_2b_2 , ab_3 and b_4 . These molecular forms possess different electrophoretic mobilities, and they correspond respectively to the LDH isozymes LDH-5, 4, 3, 2 and 1. The isozymes can be visualized by previously described electrophoretic procedures⁵.

Allelic variants at the LDH A and B loci have been reported in man¹⁵⁻¹⁸ and other mammals¹³. Analysis of the heritability of these variants indicates that the A and B loci are on autosomes. Because the variants are rare, no families which segregate variants for both A and B have been found, and the linkage of LDH A and B has not yet been determined in man. Genetically determined variants for LDH isozymes have been reported in fishes¹⁹. The number and complexity of LDH isozymes are greater in fishes than mammals, but A and B forms have been designated and homologized to the A and B forms in mammals¹⁹. Evidence that A and B variant forms segregate non-randomly²⁰⁻²² suggests that the loci are possibly linked. In mammals and birds an additional, unique form of LDH, LDH X, is expressed in testicular tissues and sperm²³. LDH X is coded by the LDH C locus. Recently, evidence has been presented that the LDH C and LDH B loci are very closely linked in pigeons²⁴. No evidence which demonstrates linkage relationships between LDH A and B in birds or mammals has been reported from genetic analysis *in vivo*.

LDH-5 homopolymers in mouse and man differ considerably in their electrophoretic mobilities and this provides good qualitative marker characteristics for mouse and human LDH A genes (Fig. 2: channels 8, 9 and 10). The LDH-1 homopolymers in mouse and man are not detectably different in their electrophoretic mobilities. The LDH B wild type mouse and human genes cannot therefore be distinguished in hybrid cells on a qualitative basis (Fig. 2: channels 8 and 10). Quantitative differences in the expression of mouse and human "b" subunits occurs, however, in the tissue cell lines used in the formation of the hybrids described here. Mouse LDH-1, 2 and 3 possess very reduced activities in the RAG cell line, and this is also true for other mouse lines such as A9 (Fig. 2: channel 9). Human "b" subunits are produced at a significantly higher rate in cell line WI-38 and other human cell lines such as KB, resulting in appreciable activity in LDH-1, 2 and 3 (Fig. 2: channel 8). Differences in activity of LDH-1 have been used to determine whether the human LDH B gene is present in hybrid cells between mouse and man³. It is possible, however, that regulatory phenomena could mimic such effects, and this makes it very desirable to use qualitative mutant forms of either the mouse or human LDH B gene for marker purposes.

An LDH B (var) allele was detected in the course of a

Fig. 1. Relationships of primary clones and derived subclones. Dates are given for the initiation of hybrids and the dates on which primary clones and derived subclones were picked.

Table 1. SEGREGATION OF LDH A AND LDH B (VAR) PHENOTYPES IN PRIMARY, INDEPENDENT CLONES OF C HYBRIDS

C	1	2	3	6	7	8	9	11	13	15	16	17	18	19	21
LDH A	-	-	-	-	-	-	-	-	-	-	-	-	-	+	-
LDH B (var)	-	-	-	-	-	-	-	-	-	-	-	-	-	+	+

(-), No enzyme activity; (+), activity.

survey of newborn babies in the New Haven population²⁵. Only one variant form of LDH B was detected in 860 individuals sampled. The homopolymer LDH B (var) migrated slightly faster than wild type human LDH-2, and at approximately the same position as mouse LDH-2 (Fig. 3: channels 2 and 4). The family of the proposita was studied, and the inheritance of the variant allele determined. If one assumes codominance, the variant segregates as an autosomal gene, in agreement with previous family studies pertaining to LDH inheritance¹⁵⁻¹⁸. The variant was expressed as a heterozygote in all individuals who possessed it.

Fig. 2. LDH zymogram showing various mouse/man hybrid phenotypes. The channels were as follows: 1-7, mouse/man hybrid extracts; 8, human tissue culture extract (KB); 9, mouse tissue culture extract (A9); 10, mouse kidney extract. The human LDH phenotypes were scored as follows: (1) LDH A⁻/LDH B (var)⁺; (2) LDH A⁻/LDH B (var)⁺; (3) LDH A⁻/LDH B (var)⁺; (4) LDH A⁺/LDH B (var)⁺; (5) LDH A⁻/LDH B (var)⁺; (6) LDH A⁻/LDH B (var)⁺; (7) LDH A⁻/LDH B⁻. Gel electrophoresis was performed in a Tris-EDTA-borate gel at pH 8.6 (see ref. 5).

The patterns of LDH expression in the J and C clones provide strong evidence that LDH A and LDH B are not linked in man: clones C-21 and J-3, which both express the human LDH phenotype LDH A⁻/B (var)⁺, provide the critical evidence (Tables 1 and 2, Figs. 2 and 3). This configuration is more informative than the phenotype LDH A⁺/B⁻, because of the heterozygous nature of the human somatic cell parent, and the fact that the non-variant form of human LDH B is electrophoretically identical with mouse LDH B. The configuration LDH A⁺/B⁻ is less informative than LDH A⁻/B (var)⁺, because the human LDH B non-variant gene could in fact be present, but incorrectly scored because of its co-migration with mouse, or because of a regulatory phenomenon. The argument for non-linkage is greatly strengthened by the occurrence of phenotypic configurations in two completely independent series of clones derived from different donors (Tables 1 and 2). The independence of the observations

Table 2. SEGREGATION OF LDH A AND LDH B (VAR) PHENOTYPES IN PRIMARY, INDEPENDENT CLONES OF J HYBRIDS

(-), No enzyme activity; (+), activity.

weakens counter arguments based on the possibility of chromosome fragmentation. The conclusion that LDH A and B are not linked is further supported by segregation of these markers in derivative secondary series of clones (Tables 3-7, and Figs. 2 and 3).

MOR	-	-	-	-	-	-	-	-	-	-	-	-	-	-

(-), No enzyme activity; (+), activity.

It could also be argued that this interpretation might be incorrect because of the possible existence of genes which regulate the expression of LDH A. For example, human LDH A and B could indeed be linked, but a third unlinked gene might either specifically suppress or activate the expression of human LDH A. Two observations contradict this. First, the action of the repressor or activator would need to be species specific, for mouse LDH A is always expressed at uniform activity levels. Second, derivative subclones from J-3 (Table 3) and J-3-Q (Table 4) do not provide an example of a transition from human LDH A (-) to LDH A (+) as might be expected if an unlinked regulator gene were segregating. These arguments are not in themselves definitive, but they strengthen the conclusion that LDH A and B are not linked.

Linkage of Human LDH B and Pep B

In all our sixty-six derivative subclones there was a positive correlation between the expression of Pep B, and either the expression of human LDH B (var) or increased LDH B activity, which is presumed to indicate the presence of the human LDH B wild type allele (Tables 3-7). Appreciable activity of isozymes LDH-1 and 2 was used as a criterion for the presence of the non-variant human LDH B gene (Fig. 3: channels 3 and 5). The analysis of this presumed linkage relationship is unfortunately complicated by the apparent distribution of the LDH B non-variant allele to all of the subclone series. Nevertheless, clones which express LDH B (var) activity invariably also possess Pep B activity.

Other interpretations of the data are possible (Fig. 4). For example, the Pep B structural gene could be linked to a regulator gene which is required for the expression of mouse and human LDH B activity (hypothesis I;

Fig. 3. Zymograms stained for LDH and Pep B activity. The slices were cut from the same gel. Channels having the same numbers represent identical samples. (1) Mouse control (A9); (2) mouse/man hybrid with an LDH A⁻/LDH B (var)⁺ human phenotype; (3) mouse/man hybrid with an LDH A⁻/LDH B (act)⁺ human phenotype; (4) mouse/man hybrid with an LDH A⁻/LDH B (var)⁺ human phenotype; (5) mouse/man hybrid with an LDH A⁻/LDH B-phenotype; and (6) human control (KB). The channels on the Pep B zymogram were similarly loaded and the human phenotypes were scored as follows: (1) mouse (control), (2) Pep B⁺, (3) Pep B⁺, (4) Pep B⁺, (5) Pep B⁺, and (6) human (control). The Pep B stain uses leucyl-glycyl-glycine as substrate²⁷.

Fig. 4; I). In that case, one would expect configurations of the type Pep B⁺/LDH B⁻ (Fig. 4; Ib). We have not observed such a combination in the J and C series of clones using activity levels of LDH B, or the presence of the LDH B (var), as criteria for the presence of human LDH B alleles. To be certain, our populations would have to be completely devoid of the wild type human LDH B allele.

One observation consistent with the linkage of Pep B and LDH B structural genes is that clones which possessed LDH B (var) activity frequently showed a concomitant increase in Pep B activity (Fig. 3), supporting a linkage involving the structural genes of Pep B and LDH B. Such a dosage relationship would not be predicted by hypothesis I (Fig. 4).

(c) 2 \uparrow LDH B 2 \uparrow Pep B	LDH B ⁺⁺ /Pep B ⁺⁺
(d) \uparrow LDH B 2 \uparrow Pep B	LDH B ⁺ /Pep B ⁺⁺

Fig. 4. Hypotheses for the segregation of linked regulatory genes and non-random segregation of chromosomes as explanations for observed associations of Pep B and LDH B phenotypes. We assume that the presence of the regulator gene is required for the expression of the specified structural gene; that is, the regulation is positive. It is further assumed that only the non-variant form of human LDH B is used. Species specificity implies that the regulator affects the activity of genes within its own genome. According to hypothesis III, the numeral "2" signifies two chromosomes bearing the designated gene. (-) signifies no enzyme activity; (+) signifies activity.

Another possibility is that a regulator gene controlling Pep B activity is linked to the structural gene for LDH B (hypothesis II: see Fig. 4; II). This model predicts a segregant class which would express human LDH but not human Pep B (Fig. 4; IIb). In our observations, the LDH B (var) expression was always associated with the Pep B expression. This result therefore contradicts the alternative hypothesis II (Fig. 4).

A third alternative to the linkage of human Pep B and LDH B structural genes is that they reside on separate chromosomes which are either retained or lost from cells always concomitantly (hypothesis III: see Fig. 4; III). The large number of clones in our study and in that of Santachiara's *et al.*⁶ rules out a chance association of this type. It could be argued, however, that the simultaneous presence or absence of the chromosomes was co-adaptive in terms of affecting cellular viability, but this is made less acceptable by the dosage relationship between LDH B (var) and Pep B (Fig. 3). The co-adaptation argument is more difficult to accept if a 1:1 multiplicity relationship must prevail between the homologue carrying the human Pep B and LDH B genes, as is the case if the model is to agree with observations which indicate a dosage relationship.

In conclusion, the hybrid clone data most simply suggest that there is a linkage between the structural genes of LDH B and Pep B in man. More definitive evidence will come from a cytological search for association between the enzyme phenotypes and a particular chromosome(s). Chromosome studies on the J series clones are now being performed.

Linkage of Additional Isozyme Markers

We have also determined the expression of the following human isozymes in many of the subclones: Pep A, B, C^{26,27}; adenosine deaminase (ADA)²⁸; glutamate-oxaloacetate transaminase (GOT)^{29,30}; glucose phosphate isomerase (GPI)³¹; glucose-6-phosphate dehydrogenase

(G6PD)³²; isocitrate dehydrogenase (IDH)³³; indophenol oxidase (IPO)³⁴; malate:NADP oxidoreductase (decarboxylating enzyme) (MOD or NADP-MDH)^{35,36}; malate:NAD oxidoreductase (MOR or NAD-MDH) (ref. 37 and unpublished work of T. B. Shows, V. M. C. and F. H. R.); and phosphoglucomutase 1 (PGM₁)^{39,40}. There was no suggestion of positive linkage between any of the additional markers (Tables 3-6). Unfortunately, no positive statement can be made regarding negative linkages, because the data are based on segregation patterns in subclones, and not all clones were examined for all markers. Taking into account these limitations of subclone analysis², a summary of the linkage relationships is presented in Fig. 5.

Human G6PD activity was observed in every subclone. The X chromosome to which G6PD is linked would be expected to be retained in all instances because it also carries the gene for HG-PRT. If we assume that human HG-PRT is present in all clones, this would indicate that X chromosome rearrangements which would segregate HG-PRT and G6PD do not occur. The absence of such rearrangements in sixty-six subclones suggests either close linkage of the two genes or a low rate of X chromosome rearrangement or both.

Chromosome Constitution of the Hybrids

Preliminary analysis of the chromosome constitution of the hybrid clones has been performed. Human chromosomes were identified on the basis of arm length measurements, and their failure to anneal with mouse satellite DNA or its complementary RNA, using *in situ* cytological annealing (unpublished procedure of M. Pardue and J. Gall and ref. 40) (Figs. 5 and 6). The modal number

Fig. 5. Phenotype association in two independent and seven derivative families of clones. Summary of segregation data shown in primary clones C and J, and secondary clones J-3, J-3-Q, J-10, J-10-M, J-10-H. Negative associations between pairs of phenotypes are measured in terms of numbers of clone series (not individual clones within a series) which show negative correlations. This was done because clones within a series may not represent independent segregation events. Zero scores indicate possible positive linkages. Many of the zero scores such as between PGM₁ and IDH are probably not significant because of absence of segregation and/or paucity of phenotype testing.

of human chromosome numbers varies between ten and sixteen in most clones. All classes of chromosomes are present, and identification of human *D* and *G* chromosomes can be obtained by the *in situ* annealing technique. Because the subclone series differ with respect to the presence or absence of LDH A, it was possible to confirm our previous linkage assignment of LDH A to a *C* group chromosome (unpublished results of C. Boone and F. H. R.). In most clones, it was possible to identify a human *C* group chromosome with arm length measurements which were consistent with those of the human *X* chromosome.

In conclusion, we agree with Santachiara *et al.*⁶ that the strategy for future linkage studies will involve the isolation of large numbers of primary, independently derived hybrid clones which can be analysed for a large number of unit markers such as antigens, isozymes, as well as chromosomes. In instances where ambiguities exist, subcloning can be used to resolve them. We believe the method will contribute powerfully to our knowledge of human gene linkage relationships.

We thank Miss E. Nichols, Miss G. Yun, Mrs S. Speer, Mrs I. Kleinman, Mrs G. Fazzalero and Mrs M. Reger for assistance; Dr J. G. Gall and Dr M. Pardue, of Yale University, for assistance with the *in situ* nucleic acid annealing of chromosome preparation; and Dr R. Davison and Dr J. A. Cortner, Division of Human Genetics, Children's Hospital of Buffalo, for help with ascertaining the LDH B variant.

We learn that Dr Westerveld and Dr Bootsma of Rijswijk, The Netherlands, using human-Chinese hamster somatic cell hybrids, have recently obtained data (unpub-

Fig. 6. Verification of human chromosome identity by means of nucleic acid annealing. Mouse bi-arm chromosomes are identified by the symbol "M"; the various types of human chromosomes by their group designations as stipulated by the London Conference¹³. Determination of human chromosome identity was made on the basis of absolute length and centromere position. Preparations were made by the air-dry method of Moorhead *et al.*¹³. The fixed, air-dried metaphase preparations were incubated with isotopically labelled RNA complementary to mouse satellite DNA. This material specifically anneals to mouse satellite DNA which is located in the centromere regions of the intact chromosomes. In autoradiograms, the chromosomes of mouse origin are isotopically labelled over their centromeres. Human chromosomes are unlabelled. The method especially permits the more certain identification of human *D* and *G* chromosomes.

lished) which confirm our observation on the independent segregation of human LDH A and LDH B loci.

Evolution of Lorises and Lemurs

by

Field studies in Madagascar and Gaboon have shown that there are many ecological and behavioural similarities between Cheirogaleinae (mouse and dwarf lemurs) and Galaginae (bush babies), which may reflect the retention of ancestral primate features. If this is so, the relationships of lemurs and lorises in previous primate classifications will need to be revised.

CLASSIFICATIONS of the order Primates attract great attention because of their special relevance to human evolution. Many different schemes have been proposed; but most work has been concentrated on relationships within major divisions and on the ranking of divisions within the Primates. The divisions themselves have remained largely unquestioned over the past 50 years, following widespread acceptance that there are six "natural groups" of living Primates: (i) Malagasy lemurs (lemur group); (ii) bush-babies, pottos and lorises (loris group); (iii) tarsiers; (iv) New World monkeys; (v) Old World monkeys; and (vi) apes and man.

Previous Classifications

The chief points of contention have been: inclusion of the tree shrews (Tupaiaidae) with the Primates¹⁻³; ranking of the Tarsiiformes (tarsier group) with either the prosimians (lemur group + loris group)¹ or the simians (monkeys, apes and man)^{4,5}; the inclusion of various fossil groups⁶⁻⁸; and the fine details of hominid (human) evolution. All authors seem to agree on a basic division between prosimians and simians and on the existence of six groups. Indeed, the tendency is to relate various fossils to one or other of these groups, without considering the evolution of the Primates as a whole. In particular,

fossils and living forms of dubious Primate status (namely the tree shrews) are typically placed with the lemurs, widely regarded as the most primitive living Primates.

Modern classifications, besides providing a useful reference system, should be consistent with supposed evolutionary relationships. The assumption that the lemur group and the loris group represent two distinct categories (variously ranked as families⁹, superfamilies, infraorders¹, or suborders^{4,10}) is clearly linked to the supposition that each of the two groups contains a range of forms derived from a distinct ancestral stock. This fact is not always clear. Confusion arises, first, because of the lack of clear guidelines in considering primate evolution³ and, second, because the published classifications are seldom accompanied by a hypothetical phylogenetic tree. Many authors hesitate to append an evolutionary tree, because much speculation is involved; but, on the other hand, the value of a classification is limited without some outline of the way a particular group has supposedly evolved.

The "ancestral Primate stock"³ is generally thought (or implied) to be located in the Upper Cretaceous and/or Palaeocene, while the existing and subfossil Malagasy lemurs are thought to have been derived from a single stock isolated on Madagascar in early Eocene times¹¹, primarily as a result of continental drift. Thus a definite

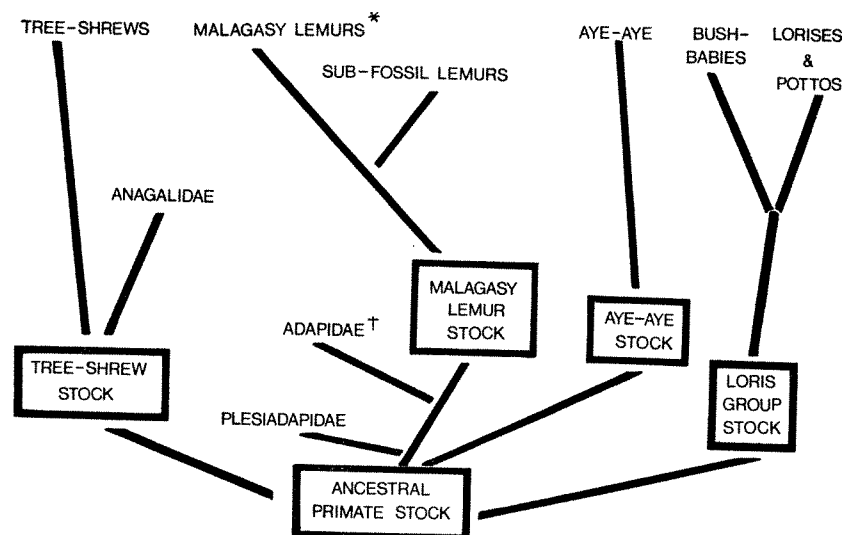

Fig. 1. One of several possible evolutionary trees for the lemurs and lorises derivable from the classification used by Simpson and Le Gros Clark. (Ancestral stocks indicate implied major subdivisions.) Note that the tree shrews, lemurs and aye-aye are placed in one infraorder (Lemuriformes), separate from the loris group infraorder (Lorisiformes).

* "Malagasy lemurs" refers to living Madagascar prosimians, excluding the aye-aye.

† The family Adapidae is frequently split into two groups: the family Adapidae (European forms) and the family Notharctidae (American forms).

Malagasy lemur stock is generally assumed to have existed in the Eocene, perhaps persisting for some time. No such clear-cut date has been suggested for the occurrence of a loris group stock, but Walker would apparently locate this in the Miocene¹². In any case, according to much current reasoning, the distinct stock giving rise to all the Malagasy lemurs (living and subfossil) must logically have been separate from the line leading to the loris group since the early Eocene.

Position of the Tree Shrews

This picture of prosimian evolution is made more complex by inclusion of the tree shrews in the Primates^{1,2}, because Simpson and Le Gros Clark both rank these mammals together with the Malagasy lemurs in the infraorder Lemuriformes, distinguishing these sharply from the loris group (infraorder Lorisiformes). If one follows this classification without the aid of a phylogenetic tree, several interpretations are possible; different patterns of relationship are consistent with the classification. One possible corollary is that tree shrews are more closely related to lemurs than the latter are to lorises, though neither author actually advocates this conclusion. An outline phylogenetic tree closer to the published opinions of these authors is given in Fig. 1, which shows that some features of the classification may be inconsistent with the probable evolution of prosimians. For example, Simpson places *Plesiadapis* as a Palaeocene relative of Malagasy lemurs in the superfamily Lemuroidea, apparently implying that many typical lemur characters (opposable digits, post-orbital bar, tooth-comb, and the like) had not been developed in the ancestral lemur/loris stock. Yet there can surely be no doubt that lemurs and lorises are far more closely related to one another than either group is to *Plesiadapis* or the tree shrews. In fact, much recent evidence shows that the tree shrews probably resemble Primates only in the retention of ancestral placental mammal characters and in the convergent development of adaptations found in many arboreal mammals. Because Simpson included *Plesiadapis* in the Primates at least partly on the grounds of comparison with (some) living tree shrews and (some) living Primates¹³, this allocation should also be reviewed.

Are the Distinctions between Lemurs and Lorises Valid?

One must now ask whether the traditional distinction between lemurs and lorises is really valid; that is, whether Fig. 1, or something close to it, represents their phylogeny accurately. If there were, in fact, a separate lemur stock and a separate loris stock, one should be able to list characters distinguishing the two. It must be assumed that these distinctions are traceable to specific, novel characters developed in one or other stock. Published lists of distinctions are almost exclusively based on living forms^{2,4,10,14}. A summary of the commonest recognized distinguishing characters is given by Weber¹⁵ (see Table 1). Hill¹⁴ gives a far more extensive list, but the same general comments apply.

Such a list should apply to all known lemurs and lorises. In fact, the list is chiefly based on comparison of living Lorisinae (loris or potto) with living Lemurinae (usually *Lemur*). The Galaginae (bushbabies) and Cheirogaleinae (mouse and dwarf lemurs) have rarely been compared with one another, and subfossil lemurs have generally been ignored. When-

ever the distinction between lemurs and lorises is examined with respect to the Galaginae and Cheirogaleinae, the initial clear separation evaporates.

Table 1. LIST OF CHARACTERS DISTINGUISHING THE LEMUR GROUP AND THE LORIS GROUP (from Weber, ref. 15, vol. 2)

Lemuridae	Lorisidae
1. Ring-shaped ectotympanic bone within auditory bulla	1. Ectotympanic bone involved in formation of bulla wall
2. Jugal in contact with the lachrymal bone	2. Jugal separated from the lachrymal bone to varying degrees by the maxilla
3. Os planum of ethmoid bone lacking in the orbit wall	3. Os planum of ethmoid bone incorporated in the orbit wall
4. Ethmoturbinal I small; does not cover the maxilloturbinal	4. Ethmoturbinal I large; covers the maxilloturbinal
5. Internal carotid artery passes through the posterior carotid foramen into the bulla, continues through bulla and enters brain cavity through the basiphosphoid bone	5. Internal carotid artery passes external to the bulla; enters the brain cavity anterior to the bulla, through the anterior lacerate foramen

To take characters from Weber's list (Table 1): in living Galaginae, a ring-like ectotympanic within the auditory bulla has been reported⁵, while our examination of skulls of the common mouse lemur (*Microcebus murinus*) shows that the ectotympanic is sometimes fused to the bulla wall. Van Kampen, usually quoted as the authority on the structure of the auditory bulla in mammals, gives no description of Cheirogaleinae or Galaginae¹⁶. It has also long been known that the Cheirogaleinae show the typical "lorisid" condition in the arrangement of the internal carotid artery and its foramina^{2,14}. Our examination of material in the British Museum (Natural History) and in our own collections shows that in Demidoff's bushbaby (*Galago demidovii*), at least, the relationship between the jugal and the lachrymal is indistinguishable from that in *Microcebus murinus*; in both, the jugal generally contacts the lachrymal. *M. murinus* and *Cheirogaleus major* and *C. medius* have an os planum in the orbit, as Le Gros Clark pointed out in a footnote². Finally, there is no significant difference between *M. murinus* and *G. demidovii* in the arrangement of the ethmoturbinals and the maxilloturbinal in the nose. In both, ethmoturbinal I is large and more or less covers

the maxilloturbinal. Weber's list, and conclusions based on such lists, must therefore be revised.

Similarities between Cheirogaleinae and Galaginae

The vital fact is that the Galaginae were not effectively compared with the Cheirogaleinae in establishing such lists. For example, Pocock¹⁰ did not study *Microcebus* in preparing his monograph, and his conclusions regarding the Cheirogaleinae were apparently based on a small number of male *Cheirogaleus*. Our field studies of *Microcebus murinus* (R. D. M.; Madagascar, 1968) and *Galago demidovii* (P. C.-D.; Gaboon, 1965-69) have shown, however, that there are many ecological and behavioural similarities between these two species:

(1) Both are nocturnal forms, sharing extensive adaptations.

(2) Preferred habitat: fine branch and creeper niche. Locomotion: mixture of horizontal running and vertical clinging and leaping (trees) or hopping (ground).

(3) Diet omnivorous: chiefly fruit and insects. Insects are typically trapped with one or both hands. There is a conspicuous predatory pattern of propulsion by the back legs, which retain their grasp, followed by rapid retraction.

(4) Both species exhibit "urine-washing"—impregnation of both hands and feet with urine, involving a complex behaviour pattern.

(5) Females associate in groups; males are usually solitary. Both sexes usually disperse for feeding. Nests used for sleeping are typically globular arrangements of leaves (interwoven), with a lateral entrance; hollow trees may be used by the mouse lemur. Home ranges around the nests are very stable.

(6) Social and parental interactions include social grooming using the tooth-comb (identical structure in both species) and grasping fur in the hands. Grooming is most common in the head and neck area.

(7) The basic categories of adult vocalizations are identical.

(8) Male home ranges apparently overlap with those of females, thus facilitating reproduction. (When the female is in oestrus, the vulva passes through a cycle of expansion, reddening and opening; during periods of sexual inactivity it is closed.)

(9) The offspring—almost identical in appearance and state of development at birth in the two species—grow slowly and are weaned fairly late. The mother carries the babies in her mouth, not on the fur. Vocalizations of the offspring are generally comparable.

Two major factual conclusions emerge from these comparisons; first, the classical morphological distinctions between lemurs and lorises do not apply to *Microcebus murinus* and *Galago demidovii*, and perhaps do not apply to the Cheirogaleinae and the Galaginae in general; and, second, the two species are extensively similar in ecology, behaviour and general morphology. There are at least four possible interpretations open to discussion: (i) the two species have retained a great number of ancestral features present in all primates before the separation of Madagascar from the African mainland; (ii) convergent evolution for adaptation to a particular ecological niche has produced an enormous number of similarities in the two species; (iii) the Cheirogaleinae and Galaginae are far more closely related than is indicated by Fig. 1 (that is to say, invasion took place across

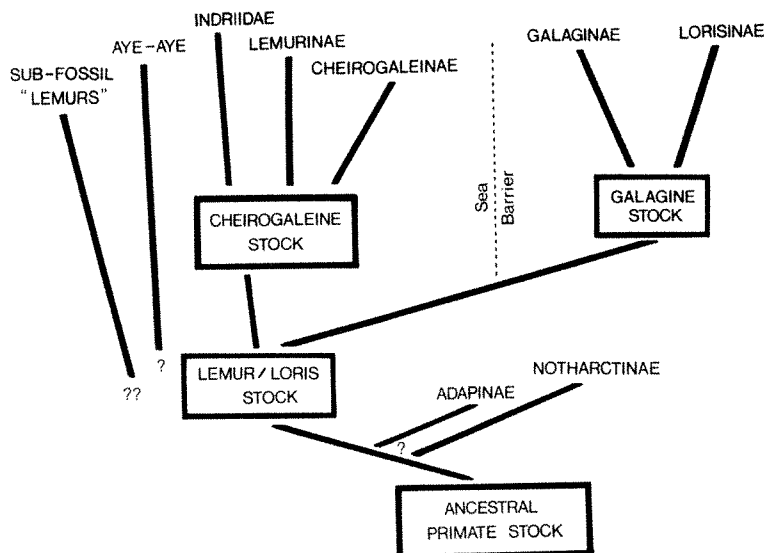

Fig. 2. A provisional outline of possible evolutionary relationships between lemurs and lorises. Note the exclusion of the tree shrews and the uncertain derivation of the subfossil lemurs (*Megaladapis*, *Archaeolemur*, and the like). The post-Eocene "sea-barrier" (= Mozambique Canal) may not have been impermeable.

the Mozambique Canal after the separation of Madagascar); (iv) some combination of (i), (ii) and/or (iii).

Cheirogaleinae and Galaginae may show Ancestral Primate Features

Because many of the similarities between the Cheirogaleinae and the Galaginae seem likely to be ancestral Primate characteristics (or at least ancestral lemur/loris characteristics), it would seem that these two groups have remained very close to the original prosimian condition (though both would, of course, have undergone subsequent specialization). Convergent (or parallel) specialization may have emphasized the similarity based on retention of ancestral features, but the chief source of similarity is probably the retention of ancestral Primate characteristics. This being the case, it is difficult to understand how one can trace the ancestry of the lemurs and lorises to anything remotely like *Plesiadapis* or ancestral tree shrews in the Palaeocene. (It should be pointed out that Simpson¹³ did not compare *Plesiadapis* with either the Galaginae or the Cheirogaleinae.)

We can provide a provisional evolutionary outline (Fig. 2), based on two assumptions: first, that no invasion of Madagascar by African prosimians (or vice versa) took place after the Eocene; and, second, that the similarity between Cheirogaleinae and Galaginae is so pronounced that explanations based exclusively on a convergence hypothesis are unsound. These suppositions may be questioned—indeed, the first, the non-invasion hypothesis, should be very closely examined—but we have attempted to give a clear statement involving wider consideration of lorises and lemurs. One possibility which we are not discussing here is that of diversification of extant and subfossil Malagasy lemurs before Madagascar split off from Africa. There could well have been several lemur types present in the African region during the late Palaeocene, and these might have given rise separately to the rather more extreme Malagasy lemurs (for example, *Daubentonius*, *Megaladapis* and *Archaeolemur*). Only new fossil evidence and extremely detailed comparisons can provide the answer.

The Eocene fossil Notharctidae, widely regarded as direct relatives of the Malagasy lemurs, probably came from a separate stock roughly contemporaneous with the hypothetical lemur/loris stock (Fig. 2).

The extremely provisional diagram of the supposed evolution of lemurs and lorises given in Fig. 2 is, in fact

fairly close to the classification given by Van Valen⁹. It is also in accordance with Romer's approach¹⁷, whereby the lemurs and lorises are regarded as forming one "natural group", rather than two intrinsically separate groups. Significantly, both authors also agree in the exclusion of the tree shrews from the order Primates^{8,17}. It must be emphasized, however, that Fig. 2 is provisional, and that post-Eocene migration across the Mozambique Canal cannot be ruled out.

The study of *Microcebus murinus* (R. D. M.) was supported by a NATO fellowship (SRC, London) and by a grant in aid for field study in Madagascar from the Royal Society. Finance and facilities for the study of *Galago demidovii* (P. C.-D.) were provided by the Mission Biologique au Gabon (CNRS; Professor P. P. Grassé).

Observations of Clear Air Turbulence by High Power Radar

by

K. A. BROWNING
C. D. WATKINS

Meteorological Research Unit,
Royal Radar Establishment,
Malvern

Clear air turbulence is a hazard to aviation and is thought to have important effects on atmospheric dynamics. This article describes the structure and evolution of clear air turbulence at high altitudes as revealed by a high power radar and vertical soundings of wind and temperature.

THEORETICAL considerations and observations in the free atmosphere suggest that clear air turbulence (CAT) is chiefly a manifestation of Kelvin-Helmholtz (K-H) instability^{1,2}. The nature of K-H instability has been clearly revealed by recent laboratory studies³, and by observations of clouds^{4,5} and of dye-tracers in the oceanic thermocline⁶. K-H instability is a form of dynamic instability produced within a hydrostatically stable flow in the presence of sufficiently strong vertical shear. It appears as amplifying waves ("billows") oriented perpendicular to the shear vector, into which the vorticity is concentrated, and which eventually "break" into turbulent flow on a range of smaller scales. The onset of K-H instability over an atmospheric layer of depth Δz is determined by the Richardson number

$$Ri = (g/\theta)(\Delta\theta/\Delta z)/(\Delta u/\Delta z)^2 \quad (1)$$

where Δu is the vector wind change over the depth Δz and θ is the potential temperature. Ri is a ratio of work done against gravity in vertical motions and the kinetic energy available for disturbances from the shear of the mean flow. Theoretical studies⁷ indicate that $Ri \leq \frac{1}{4}$ is a necessary but not sufficient condition for the onset of K-H instability. For a sheared layer of finite thickness, the spacing of the resulting K-H billows corresponds to the maximum unstable wavelength⁸ given by

$$\lambda = (\pi/g)(\Delta u)^2/(\Delta\theta/\theta) \quad (2)$$

As pointed out by Ludlam⁴, the nature of the bumpiness experienced by an aircraft encountering K-H billows depends on the part of the billow pattern traversed by the aircraft, its heading with respect to the wind shear vector, and also the response characteristics of the aircraft. Ludlam suggests that in the early stages of the evolution of billows the changes in vertical air velocity encountered over horizontal distances equal to Δz might have a magnitude similar to Δu . In some cases this can exceed 20 m s⁻¹.

K-H instability and associated turbulence in the clear atmosphere can be observed with high power radars. This article reviews the principles of radar detection of CAT and then presents some combined radar and radio-sonde observations showing the structure and evolution of

a region of CAT associated with a well defined case of K-H instability.

Radar Detection of Clear Air Turbulence

Studies of the optically clear atmosphere using high power radars with wavelengths of 100 mm and longer have revealed echoes due to incoherent backscatter from inhomogeneities of refractive index⁹. Although in the lower troposphere these inhomogeneities are chiefly due to gradients of humidity, at higher levels they are the result of strong gradients of potential temperature. Clear air radar echoes in the upper troposphere are almost invariably associated with layers of strong static stability within which the potential temperature increases rapidly with height. The presence of turbulence within such layers gives rise to irregularly disposed inhomogeneities of refractive index, and this results in incoherent backscatter from a large number of independent scatterers. Although the inhomogeneities occur over a range of scales, constructive interference occurs only from inhomogeneities separated by half the radar wavelength ($\lambda/2$). Thus the radar effectively singles out the particular Fourier component of the refractive index spectrum that is directed along the beam axis and the wavelength of which is half the radar wavelength.

The scattering of electromagnetic waves by refractively turbulent regions has been treated fully by Tatarski¹⁰ on the assumption that the radar-observed scale is within an "inertial subrange" in which the turbulence is locally homogeneous and isotropic, with an energy spectrum that obeys the Kolmogorov $k^{-5/3}$ law, where k is the wave number. Atlas, Hardy and Naito¹¹, and Ottersten¹², in applying Tatarski's results to the atmosphere, have shown that the radar reflectivity (backscattering cross-section per unit volume) of a refractively turbulent layer is given by

$$\eta = 0.38 C_n^2 \lambda^{-1/3} \quad (3)$$

where C_n^2 is a measure of the intensity of the refractivity fluctuations given by

$$C_n^2 = a^2 M^2 L_0^{4/3} \quad (4)$$

Fig. 1. *a*, Series of tracings of RHI radar photographs at intervals of roughly 2.5 min from 1243 to 1258 GMT showing the development and breakdown of Kelvin-Helmholtz billows on a clear air echo layer. The reflectivity of the clear air layer at 1243 GMT was very weak in the region where it is drawn dotted. Successive tracings are displaced in the vertical by distances proportional to time. Identifiable portions of the train travelled parallel to the dashed line XY. *b*, RHI radar photographs showing the portions of the clear air layer labelled AB, CD, and EF in *a*.

In equation (4), a^2 is a non-dimensional constant, M is the mean vertical gradient of (generalized) potential refractive index, and L_0 is the outer scale of the inertial subrange. For a given vertical wind shear the outer scale is a measure of the intensity of turbulence. Thus C_n^2 , and hence the measured value of radar reflectivity, depends on the intensity of turbulence within the inertial subrange (either at the time of the reflectivity measurement or perhaps a short time earlier).

The outer scale of the turbulence responsible for the radar echo is probably limited by the depth of the echo layer. Recent radar measurements at ultra high resolution of the echo at the top of the planetary boundary-

layer show that this can be very small, typically 10 m (unpublished work of Atlas *et al.*). This order of magnitude is corroborated by refractometer soundings¹², which suggest that a depth of 30 m is typical for the intense refractivity fluctuations at the top of the boundary-layer. Echo layers at high altitudes may be rather deeper; the available measurements, however (including those presented here), are of relatively poor spatial resolution and all that can be said with certainty is that the depth of high altitude layers is often less than 150 m. Thus, although a high reflectivity implies the existence of turbulence on small scales, it does not in itself necessarily imply the simultaneous presence of CAT on the larger scales important in aircraft operations (100–1,000 m). Indeed, on occasions when the clear air echo layers are seen to be level and devoid of structure, they provide evidence of the absence of large scale CAT at least in their immediate vicinity. Frequently, however, clear air echo layers do show irregularities; these are often wavelike or in the form of billows, sometimes with vertical amplitudes of several hundreds of metres. In these circumstances the layer echoes serve as valuable tracers of the larger scale motions which are responsible for the more intense CAT occurrences.

There are two ways of exploiting these tracers to provide insight into the nature of CAT. One is to measure the velocity characteristics of the radar echo by Doppler techniques. The other is to observe the structure and evolution of the perturbed echo layer. The latter approach was first used extensively by Hicks and Angell¹³ and Hicks¹⁴, who obtained photographs showing clear air echo layers perturbed by K-H billows. The billows attained crest-to-trough amplitudes of up to 600 m, across which the total wind change was several metres per second, so that any aircraft encountering them could have expected to encounter significant CAT. Unfortunately no data were obtained showing the life cycle of K-H billows. Atlas *et al.* in their unpublished studies of clear air echo layers have obtained time sequences of data showing successions of K-H billows at different stages of development and breakdown. But their data are Eulerian in the sense that different waves were being observed as they drifted through a fixed radar beam. Thus again it was not possible to interpret the data unambiguously in terms of the life cycle of individual waves. The observations reported in what follows show at least part of the Lagrangian time history (following the motion, that is) of a recognizable patch of CAT associated with K-H billows.

Evolution of a Patch of Clear Air Turbulence

We used the high power S-band radar at the Royal Radar Establishment site at Defford, Worcestershire (2° 09' W, 52° 06' N). The radar consists of a coherent magnetron transmitter and low noise receiver used in conjunction with one of a pair of fully-steerable paraboloid aerials originally designed for radio astronomy studies. Some characteristics are summarized in Table 1.

Assuming the pulse volume to be about half filled, the radar parameters in Table 1 imply a minimum detectable reflectivity η_{\min} of about $5 \times 10^{-15} \text{ m}^{-1}$ at 10 km range (neglecting any advantages gained from photographic integration). One of the chief factors limiting η_{\min} at close ranges is the obscuration caused by backscatter from ground targets detected in the antenna side lobes.

Table 1. CHARACTERISTICS OF THE DEFFORD RADAR

Wavelength	107 mm
Transmitted peak power	~1 MW
Pulse repetition frequency	800 s ⁻¹
Pulse length (in space)	1.3 μ s (200 m)
Total system noise temperature (using a parametric amplifier)	~250 K
Aerial diameter	25 m
Half power beamwidth	0.33°
Maximum azimuth scanning rate	72° per min
Maximum elevation scanning rate	36° per min
Present data recording system	Photography of RHI display

Fig. 2. Time-height pattern of the vertical gradient of potential temperature, based on four radiosonde ascents from Pershore. Note the splitting of the statically stable layer following the occurrence of deep Kelvin-Helmholtz instability.

In the present system this problem is diminished by using (i) a Cassegrain feed to minimize side lobes, and (ii) an MTI system to discriminate against stationary targets.

The normal mode of operation in studies of high altitude CAT is for the radar to be scanned continuously in a vertical section along the direction of the upper tropospheric winds. The received echoes are displayed and photographed on a conventional range-height-indicator (RHI) display. Interpretation of the radar data was aided by special hourly radiosonde ascents from RRE Pershore (8 km north-east of the radar) giving vertical profiles of temperature, humidity and wind speed and direction.

The observations reported here were obtained in cloudless conditions on February 6, 1970, as part of a 10 h sequence of measurements made while a weakening northerly jet was overhead in the upper troposphere. Maximum wind velocities of about 50 m s^{-1} from a direction 010° east of north occurred at a height of about 9 km. Strong vertical wind shears and high static stability occurred both above and below the jet, and clear air layer echoes were detected in these regions throughout much of the observational period. Layer echoes were occasionally perturbed by K-H billows. The full analysis relating the occurrence and structure of the clear air echoes to the temperature and wind shear patterns will be published elsewhere; this article is restricted to a consideration of one of the more clearly documented occurrences of CAT, which took place within a layer of particularly strong shear and stability (that is, a frontal zone) beneath the jet core. At 1243 GMT on February 6 a weak clear air echo was centred within this layer near 6 km; shortly afterwards, as shown by the sequence of radar data in Fig. 1, this echo intensified and was seen to be perturbed by large-amplitude K-H billows.

The radar sections shown in Fig. 1 were orientated along 010° . This direction was within 20° or 30° of both the direction of the wind at the middle of the echo layer (350°) and the direction of the vertical wind shear vector across the echo layer (030° changing to 040° after the occurrence of the billows). Because K-H billows take up an orientation at right angles to the wind shear and travel at the velocity of the winds in the middle of the sheared layer, the orientation of the radar sections was a suitable compromise which revealed practically the true wavelength and which at the same time permitted individual billows to be followed for some time as they approached the radar. Identifiable parts of the train of billows

travelled approximately along the dashed line XY in Fig. 1a. The slope of this line corresponds to a line-of-sight velocity component of 13 m s^{-1} . Pronounced billows were first observed at long ranges (AB in Fig. 1), where their crest-to-trough amplitude was between 300 and 400 m and their wavelength was between 3 and 5 km. Subsequently these same billows were observed to complete their life cycle as they approached the radar, finally giving rise to a double echo layer at 1258 GMT. The detailed evolution of the echo pattern is discussed later.

The radiosonde ascents reveal some of the effects of the intense K-H instability depicted in Fig. 1. The most striking effect (shown in Fig. 2) was the splitting of the layer of strong static stability (that is, large $\Delta\theta/\Delta z$) between the times of the first two radiosondes. Radiosonde No. 1 was launched at 1207 GMT, some 36 min before the first radar observation of K-H billows; radiosonde No. 2 was launched at 1309 GMT, some 11 min after the clear air echo had split into two distinct layers. Both radiosondes ascended through the 6 km level 15 min after launch in a position 15 km due east of the Defford radar. $\Delta\theta/\Delta z$, $\Delta u/\Delta z$ and Ri have been evaluated for both of these soundings over layers 200 metres deep.

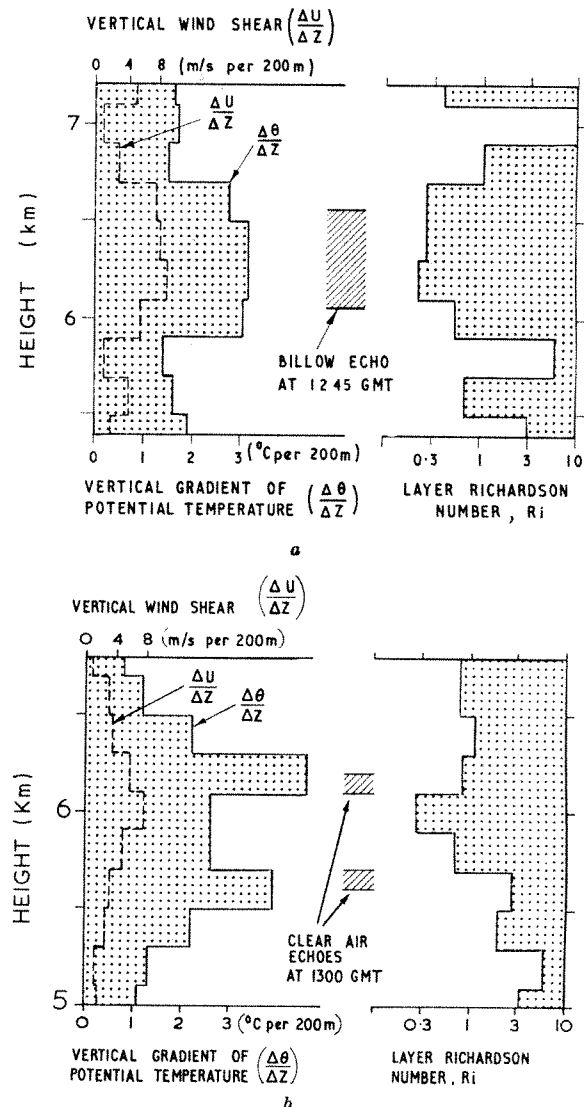

Fig. 3. Profiles of the vertical gradient of potential temperature $\Delta\theta/\Delta z$, the magnitude of the vertical vector wind shear $\Delta u/\Delta z$ and Richardson number, all measured over 200 m height increments. The profiles in *a* and *b* are based on radiosondes No. 1 and 2, launched from Pershore at 1207 and 1309 GMT, respectively. The clear air radar echoes indicated correspond to the vertical extent of the Kelvin-Helmholtz billows at 1245 and to the resulting double layer seen at 1300 GMT.

Fig. 4. Schematic representation of the life cycle of an individual Kelvin-Helmholtz billow based on the data in the earlier figures. Time progresses from right to left. Thick lines correspond to the detectable clear air radar echo, which started as a single layer at 1243 and finished as a double layer at 1258 GMT. Schematic vertical profiles of $(\Delta\theta/\Delta z)$ are indicated before and after the occurrence of Kelvin-Helmholtz instability.

The results are plotted in Figs. 3a and b, which show that there was a close correspondence (1) between the initial deep layer of strong static stability and the height of the K-H billows and (2) between the resulting two layers of strong static stability and the height of the double echo layer. (Because there was a small time difference between the radiosonde and radar observations, the indicated heights of the radar echoes in Fig. 3 have been adjusted slightly to take into account the lowering of the overall stable layer). The profiles of $\Delta u/\Delta z$ in Fig. 3 indicate strong shear near the stable layer in both soundings. Although there is no evidence in the second sounding of a split in the shear profile similar to that observed in the stability profile, there was a slight overall decrease (and veer) of the wind shear. As a result the Richardson number, which was between 0.24 and 0.29 over a depth of 600 m before the onset of K-H instability, generally increased (except within a shallow 200 m height interval between the two stable layers).

Interpretation of the Observations

The observations depict several aspects of the evolution and effects of intense Kelvin-Helmholtz instability in the atmosphere. The life cycle of the K-H billows is summarized schematically in Fig. 4, which has been adapted from a diagram by Scorer¹⁵. The starting point, at the right of the diagram, shows a single unperturbed clear air echo layer of limited vertical extent (< 150 m). This was embedded within a deeper (800 m) stable layer across which there was a strong vector wind change (30 m s^{-1} over 800 m, with a 16 m s^{-1} change between 6.1 and 6.5 km). The Richardson number measured over 200 m layers was close to the critical value of $\frac{1}{4}$ over a depth of 600 m for some time before the development of the deep K-H instability. The shallowness and the unperturbed appearance of the echo layer at this time suggest, however, that the intensity of turbulence was then relatively slight.

The layer echo began to show signs of distortion by K-H billows at 1243 GMT. The subsequent development of the pattern of radar echoes associated with the billows can be accounted for in terms of the laboratory observations of Thorpe³. According to Thorpe there is a rapid redistribution of fluid within the dynamically unstable layer as the disturbance grows. At the centre of the rolls there is an accumulation of fluid and a decrease in the gradient of potential temperature; between the rolls there is a sharpening of the gradient of potential temperature. The increased gradient of potential temperature and hence of refractivity in these parts is partly responsible for the more than four-fold increase in reflectivity of portions of the radar echo observed between 1243 and 1248 GMT. Likewise the decreased gradients within the rolls also account for the reflectivity in these parts dropping below the threshold of detectability. By 1250 GMT turbulent mixing initiated within each roll had spread to form cellular (cat's eye) patterns in which the static stability was more nearly neutral. The resulting redistribution of stability was such as to concentrate the stability into two layers, at the top and bottom of the mixed regions¹⁶. These stable boundaries were detected by the

radar, and they produced the so-called braided echo pattern first reported by Hicks and Angell¹³. The final stage in the evolution was for the cells of relatively well mixed air resulting from the breaking of each billow to be stretched out by the wind shear. For a while the radar continued to detect the edges of these regions as sloping filaments of echo, but by 1258 GMT these regions had merged to give a practically homogeneous and horizontal layer 400 to 500 m deep, bounded by two very stable layers detected by the radar as a double layer. (An associated splitting of the wind shear profile was not observed.) Thereafter the double layer of both stability and radar echo persisted for more than 2 h (Fig. 2). Further major splitting did not occur during this time. The distance separating two split layers depends on the amplitude of the billows and on the degree of entrainment across the stable boundaries during the decay of the turbulence⁶. In the present case the final separation was not much greater than the crest-to-trough amplitude of the initial billows. The implied small amount of entrainment is probably a consequence of the strong overall static stability causing the turbulence to decay rapidly.

The vector wind change across the 400 m depth of the billows was shown by the radiosonde data to be as great as 16 m s^{-1} before the onset of the deep K-H instability, and so, according to the criterion of Ludlam⁴, the billow phenomenon almost certainly corresponded to a situation of intense CAT. The present radar equipment is being modified to give Doppler information and when this is achieved it will be possible to obtain a quantitative assessment of turbulence intensity from the radar alone. Thus it is evident that high power radar has considerable potential as a research tool for studying the physical mechanisms associated with atmospheric turbulence and its relationship with larger scale meteorological processes¹⁷. After a long period in which it has been necessary to treat all turbulence statistically (as locally homogeneous, isotropic and stationary), observations by high power radars and by other means are helping to focus attention on ordered motions as the source of intense clear air turbulence.

Polarization-wavelength Profile of the Interstellar 4430 Å Absorption Band

KNOWLEDGE of the scattering and polarizing properties of interstellar grains has now reached the stage where very specific models are being proposed for the composition and size distribution of these grains. It is evident that high resolution studies of the wavelength dependence of interstellar extinction and polarization will provide important tests of the proposed grain models. Although much work has been done on detailed studies of interstellar extinction, the detailed wavelength dependence of interstellar polarization at a higher resolution needs more study. Another related problem concerns the possibility that the diffuse interstellar bands, the most

The Wollaston prism which splits the incident starlight into two beams, polarized in mutually perpendicular planes, was placed in an adjustable mounting above the spectrograph slit. The angle between the emergent rays is 5.8 minutes of arc, corresponding to a separation of 0.3 mm on the plates (Fig. 1). The observations were made on the star 55 Cyg (HD 198478, B3_{1a}, $E_{B-V}=0.57$) at a dispersion of 40 Å mm⁻¹, this star having been studied by one of us¹ for the absorption profile of the 4430 band. The emulsion used was Kodak IIa0. Pairs of orthogonally polarized spectra were recorded for three different positions of the Wollaston prism. In order to obtain corrections for instrumental polarization, the unpolarized star Vega (α Lyr, HD 172167, A0V, $E_{B-V}=0.00$) was observed in the same way. Five pairs of spectra for each star and for each position of the Wollaston prism were obtained.

Calibrations were imposed by the calibration spectrograph associated with the 36-inch telescope. The spectra were measured over the wavelength region 4620 Å to 4380 Å in terms of Baker density, defined as

$$\Delta = \log_{10} \left(\frac{1}{T} - 1 \right)$$

T being the transparency. This function of T is known to be closely linear with magnitude². The spectral resolution is 4 Å, and the slope of the calibration curve was found to be constant over the spectral range measured.

Fig. 1. Pairs of spectra, plane polarized by Wollaston prism.

intense of which occurs at 4430 Å, may be polarized differently from the neighbouring continuum: the amount and nature of this difference, if any, may give a clue to their origin. Spectrophotometry of these bands is always difficult because of the width and shallowness of the features, and polarization studies are correspondingly more difficult. By the use of a Wollaston prism at the Cassegrain focus of the 36-inch telescope of the Royal Observatory, Edinburgh, we have been able to derive a polarization profile across the 4430 band. This report describes the method and presents the preliminary results.

Fig. 2. Wavelength dependence of the degree of interstellar polarization across the 4430 Å absorption band. The broken line indicates the mean value for the spectral region away from the band.

Because Vega is unpolarized, the pairs of spectra should be identical. Any difference would indicate the presence of instrumental polarization which, of course, must be taken into account to interpret the results of 55 Cyg. It is found that the differences $\delta\Delta$ between the pairs of spectra for Vega are linear with $1/\lambda$ and have a small inclination with the abscissa, indicating that instrumental polarization is present, although small, and those for 55 Cyg show signs of an underlying profile. To evaluate the degree of polarization we found the difference of the values of $\delta\Delta$ for 55 Cyg from the corresponding values for Vega. These differences were multiplied by the slope of the calibration curve to derive the monochromatic magnitude differences.

For partially plane polarized starlight, the magnitude difference Δm_γ between the two orthogonally polarized spectra in each pair is given by

$$0.46 \cdot \Delta m_\lambda = P_\lambda \cos 2\varphi \quad (1)$$

where P_λ is the degree of polarization, and

$$\varphi_\lambda = \alpha - \theta_\lambda \quad (2)$$

where α and θ_λ are the direction of polarization of the Wollaston prism and the position angle of interstellar polarization, each measured with reference to a sky oriented axis.

Let $\Delta m'_\lambda$ be the corresponding magnitude difference when the Wollaston prism is rotated by an angle x . P_λ and φ_λ are then given by

$$\varphi_\lambda = \frac{1}{2} \tan^{-1} \left(\cos 2x - \frac{\Delta m'_\lambda}{\Delta m_\lambda} \right) / \sin 2x \quad (3)$$

$$\text{and} \quad P_\lambda = 0.46 \cdot \frac{\Delta m_\lambda}{\cos 2\varphi} \quad (4)$$

The results are presented in Fig. 2, which shows the detailed wavelength dependence of the degree of polarization in the spectral region from 4620 Å to 4380 Å. In the continuum away from the 4430 feature, the degree of polarization is 2.7 per cent; we see, however, that this changes across the spectral region affected by this feature, the maximum polarization being observed at $\lambda \sim 4450$ Å. There is no significant variation of the position angle θ within the measured wavelength range, its numerical value in equatorial coordinates being $3^\circ \pm 10^\circ$.

Coyne and Gehrels³ have measured the polarization of 55 Cyg at several wavelengths in the range 0.3–1.0 μ m. The percentage polarization that they derived is $P_v = 2.68$ at $v = 4292$ Å and $P_r = 2.89$ at $\lambda = 5128$ Å, and the position angles in equatorial coordinates are $1^\circ.4$ and $2^\circ.0$ respectively. The present results are in adequate agreement (see Fig. 2). The fact that the polarization changes over the spectral region of the 4430 interstellar band implies that the band is polarized differently from the continuum, and the 4430 process involves polarization as well as extinction. This conclusion then indicates that the explanation of the 4430 process in terms of gaseous absorption may not be tenable.

We would like to emphasize, however, that these results are preliminary and have to be confirmed by further observation. An extensive programme of measuring the detailed wavelength dependence of interstellar polarization is under way.

Galactic Component of the Diffuse X-ray Background

Cooke, Griffiths and Pounds¹ have recently detected an increase of intensity of the cosmic X-ray background in directions close to the galactic plane, indicating the possible existence of a diffuse galactic X-ray component. The similarity of this galactic component, in both intensity and spectrum, to the general isotropic background would tend to suggest a possible causal connexion. This report argues that interstellar dust occurring near the galactic plane would scatter the isotropic background so as to produce the observed phenomenon.

The existence of a diffuse background of optical radiation close to the galactic plane has been known for many years and is usually attributed to the scattering of starlight by interstellar grains²⁻⁴. The same grains would also scatter X-rays from a cosmic background as well as from

discrete sources. For grains of radius a the scattering cross-section σ for X-rays of wavelength λ is defined by the equations^{5,6}

$$\left. \begin{aligned} \sigma &= Q(\rho) \pi a^2 \\ \rho &= 2N \left(\frac{e^2}{mc^2} \right) a \lambda \\ Q(\rho) &\cong 2 \text{ if } \rho \gg 1 \\ Q(\rho) &\cong 2\rho^2 \text{ if } \rho \ll 1 \end{aligned} \right\} \quad (1)$$

Here e, m are the electron charge and mass, and N is the total electron density in the material, $\sim 10^{24} \text{ cm}^{-3}$ for most solids. For grains of radii $\sim 3 \times 10^{-5} \text{ cm}$ the cross-section σ given by the formulae varies from $\sim \pi a^2$ to $\sim 0.01 \pi a^2$ over the waveband observed by Cooke *et al.*¹ ($\sim 6 \text{ Å} - 0.6 \text{ Å}$); and for grains of radii $\sim 3 \mu\text{m}$ the cross-section remains close to $\sim \pi a^2$ over the same waveband. The phase function for the scattering of X-rays is very strongly forward throwing, the scattering being almost entirely directed into a cone of semi-angle $\sim \lambda/2a$ (ref. 6).

At optical wavelengths the extinction coefficient of the interstellar medium is ~ 2 magnitudes per kpc in directions close to the galactic plane. Because the optical extinction efficiency of grains could be high ($Q \approx 4$ in some cases⁷) it follows from our earlier remarks that the X-ray scattering coefficient of the interstellar medium could be as high as

$$\kappa_{\text{scat}}(6 \text{ Å}) \sim 1 \text{ magnitude kpc}^{-1} \quad (2)$$

at $\lambda \sim 6 \text{ Å}$. At the shorter wavelengths, $\lambda \sim 0.6 \text{ Å}$, the scattering coefficient is likely to be dominated by the relatively small fraction of 1–3 μm grains that may be present. If such grains contribute ~ 10 per cent to the optical extinction it is likely that

$$\kappa_{\text{scat}}(0.6 \text{ Å}) \sim 0.1 \text{ magnitude kpc}^{-1} \quad (3)$$

The mean X-ray absorption cross-section of the interstellar gas per H atom is (ref. 8)

$$\sigma_E \approx 4 \times 10^{-22} (\lambda/12.4 \text{ Å})^{8/3} \text{ cm}^2 \quad (4)$$

With a mean atomic hydrogen density $\sim 1 \text{ cm}^{-3}$ the X-ray absorption coefficient is thus

$$\kappa_{\text{abs}} \sim (\lambda/12.4 \text{ Å})^{8/3} \text{ magnitude kpc}^{-1} \quad (5)$$

From relations (2), (3) and (5) it is clear that the albedo of interstellar matter is close to unity throughout the X-ray waveband observed by Cooke *et al.*¹

Following Henyey and Greenstein² I consider an infinite plane parallel slab model of the Galaxy of total X-ray optical depth $2\tau_1$ with the Sun situated in the mid-plane. Let I be the intensity of unscattered diffuse cosmic X-rays, assumed constant at every point in space. The intensity of once-scattered X-rays arriving at the location of the Sun from a direction making angle θ with the galactic plane is

$$I_1(\theta) \cong \gamma(1 - e^{-\tau_1 \cos \theta}) \int \Phi d\omega \quad (6)$$

where γ is the albedo and Φ is the phase function for scattering normalized so that

$$\int \Phi d\omega = 1$$

Assuming I to be approximately isotropic, equation (6) gives

$$I_1(\theta) \approx \gamma(1 - e^{-\tau_1 \cos \theta}) I \quad (7)$$

as a first order solution to the scattered component of the diffuse X-ray background. (The contribution to I from discrete sources has been neglected here, but the data currently available on sources suggest that its inclusion will not alter our general conclusions.)

From relation (7) with $\gamma \approx 1$ we obtain $I_1(\theta) \approx I$ in directions close to the galactic plane, as observed by Cooke *et al.*¹. The direction for which $I_1(\theta)$ falls to $\sim I(0)/2$ is defined by $\theta \approx 2\tau_1$, so that the observed angular extent of the galactic background $20 \lesssim 6^\circ$ is obtained if $\tau_1 \lesssim 0.03$ at X-ray wavelengths. Because we have $\tau_1 \approx 0.1$ at optical wavelengths^{2,3} it is likely that a value $\lesssim 0.03$ may be

appropriate for the X-ray region relevant to the present discussion. From relation (7) it is also clear that the wavelength dependence of I_1 must be closely similar to that of I for directions very close to $\theta \sim 0$. Because τ_1 is likely to decrease with increasing energy, the present model predicts that the angular spread of the diffuse galactic X-ray background decreases with increasing photon energy.

Electron Correlations and Solar Neutrino Counts

EXPERIMENTS to detect the neutrino flux from the Sun could be used to test the basic hypotheses concerning the internal constitution of the Sun and the nuclear fusion reactions believed to be occurring in its interior. The measurements of Davis, Harmer and Hoffmann¹ give an upper bound on the neutrino counting rate which is approximately half of the theoretical rate calculated by Bahcall, Bahcall and Shaviv², and an order of magnitude smaller than theoretical rates obtained by other authors. Before the discrepancy between theory and experiment can be accepted as requiring a radical change in the theory of stellar structure, it is first necessary to reduce the uncertainties and poor approximations contained in the "constitutive relations" of the theory; that is, in the equations for the nuclear reaction rates, the pressure and the opacity³, each expressed as a function of density, temperature and chemical composition of the medium. In current tables⁴ of solar opacity, the contribution from the scattering of radiation by free electrons is calculated under the unjustified assumption that the plasma of the solar interior can be treated as a perfect classical gas, and hence that the scattering cross-section is given simply by the classical frequency-independent Thomson cross-section $N_e\sigma_t$, for N_e independent electrons in the plasma. This report shows that corrections to σ_t produced by classical⁵⁻⁷ and quantum⁸ electron correlations reduce the electron-scattering opacity in the core of the Sun by approximately one-third, and that this leads to a significant reduction in the theoretical neutrino flux.

The percentage deviations from σ_t resulting from electron correlations (classical plus quantum corrections) in the variable-composition model of Bahcall *et al.*² are given in Table 1. The domain considered extends from the centre out to 0.33 of the solar radius, and contains 0.69

of the solar mass and the energy generation region. The quantity b is $\lambda_i/(4\pi\lambda_{De})$ where λ_i is the wavelength of radiation at the black-body maximum; the classical plasma parameter is

$$\Lambda = \beta e^2 / \lambda_D \simeq 2\pi^{1/2} e^3 \beta^{3/2} n_j^{1/2} (3+X)^{1/2} (1+X)^{-1/2}$$

where $\lambda_D^2 = 4\pi\beta e^2 \sum n_j Q_j^2$, and Q_j is the charge on species j (the term with $Q_j = -1$ defines λ_D^2); and the cross-sections $\delta\sigma$ are straightforward generalizations to a multi-component system of those given previously⁶ for pure hydrogen models. In performing the integration over solid angle to obtain total cross-sections I have not inserted the weight factor $(1 - \cos \theta)$, where θ = scattering angle, suggested by Watson⁷, because no proof has been given that the factor is necessary for the case of a non-relativistic system of scatterers. The effect of correlations has been taken into account to order (e^2, z^2) in perturbation theory, where $z = \exp(\beta\mu)$ is the fugacity and μ the chemical potential of the electrons. It is seen that the system falls neatly into the near-classical domain^{8-10,21} of the statistical mechanics of interacting particles. At the centre the quantum parameter $\zeta = 4\pi^{3/2} n_e \lambda^3$ reaches its maximum value permitted by the small z approximation. Because this value is somewhat larger than that considered previously⁶, however, the shift in fugacity resulting from quantum statistics and interactions should be included. For simplicity of computation I have taken $z \simeq z_0(1 - \Lambda/2 - \zeta(\beta e^2/\lambda)/(2\pi)^{1/2})$, where the second and third terms on the right-hand side are, respectively, approximations to the first-order direct and exchange corrections to the quantum ideal gas fugacity $z_0 = e^{\beta\mu_0} \simeq \zeta(1 + \zeta(2(\sqrt{2} - \zeta))^{-1})$. At the outer limit of the solar region considered the quantity $\beta e^2/\lambda$ is still within the approximate upper bound of 0.35 suggested by the calculation¹¹ of the zero-range pair correlation function for arbitrary values of $\beta e^2/\lambda$ in an ionized system. Because $\Lambda \ll 1$, the Debye term $\delta\sigma_D$ gives a good approximation for the classical correlations. The zero-order exchange term $\delta\sigma_0^x$ has been calculated by expanding the London-Placzek¹² pair correlation function, with the appropriate spin factor, to order z^4 .

The total result is to reduce the effective cross-section by an amount which is almost constant over the whole solar domain considered, and which is equal to 34.5 per cent at the centre. Consequently, it can be seen from the energy transport equation¹³ that the temperature gradient in the core is reduced, and because the rates of nuclear reactions are highly sensitive to the value of the ambient temperature, a non-negligible modification to the neutrino flux is expected. A bonus side-effect of the reduction in temperature gradient is that the assumption that energy transfer in the core occurs by radiation rather than convection becomes more plausible. An estimate of the modification to the neutrino flux follows immediately from the work of Bahcall, Bahcall and Ulrich¹⁴. These authors computed the effect on the solar model of Bahcall *et al.*² of hypothetical localized deviations in the opacity κ , given by

$$\kappa(\text{perturbed}) = f(T)\kappa(\text{standard})$$

where $f(T) - 1 = \alpha\{1 + 100((T - T_0)/(T + T_0))^{2.1} - 1\}$ is an arbitrary smooth function of T which reaches a peak value of

ρ = Mass density, X = mass fraction of hydrogen, $\lambda = h/(\beta/2m)^{1/2}$, $\beta = (k_B T)^{-1}$.

α at $T=T_0$ (variable). We compare the hypothetical deviation $f(T)-1$ for the case $T_0=14\times 10^6$ K and $\alpha=-0.2$ with the real deviation obtained from Table 1 by assuming that the electron-scattering process contributes one-third of the total opacity after correlations have been taken into account. Then, if electron correlations are the only source of deviation from the standard values of core opacity, one can immediately estimate a reduction in the value of the theoretical neutrino counting rate of 30 to 40 per cent, and a fair match between theory and experiment would be obtained. Recently, however, increases have been found for the opacity contributions from autoionization lines¹⁵, ordinary lines¹⁶ and bound-free transitions¹⁶. The first two increases need not disturb us overmuch because they are only appreciable at relatively low temperatures. In the latter case, however, uncertainties^{17,18} in the accepted photospheric abundance of iron leave open the possibility that a large increase in opacity in the core might be obtained from the bound-free absorption of radiation by highly ionized iron¹⁹, assuming that photospheric and core abundances of iron are related. Such a result could more than offset the decrease in neutrino rate resulting from electron correlations. It is clear now that before one can talk seriously of "predicting" the solar neutrino flux, the details of the elementary physical processes contributing to the opacity, as they occur in a real plasma at the appropriate density and temperature, have to be understood. Together with some uncertainties in neutrino production rates and absorption cross-sections¹⁴, the major unknown would then be the chemical composition of the core, and a more realistic estimate of the latter might be obtained by considering gravitational separation of the elements of high atomic number²⁰. Although the neutrino rate seems to be two or three times more sensitive to hypothetical deviations in the equation of state¹⁴ of the solar core than in the opacity, the actual deviations in the equation of state are far smaller than the hypothetical ones ($\alpha=\pm 0.1$), provided (and this may not be true²⁰) electron correlation effects are the only omissions. Because Bahcall *et al.*¹⁴ have already taken into account the zero-order exchange and classical Debye term in their "standard" equation of state, the principal term remaining is the first order exchange¹⁰ term $\simeq -\pi n_e \lambda^3 (\beta e^2/\lambda) \simeq -0.005$ (the classical ideal gas contribution is unity), at the "sensitive" temperature¹⁴ of 8×10^6 K. The uncertainty-principle term²¹ is of order e^4 , and can be neglected.

Lateral Extension in the East African Rift Valleys

MCKENZIE *et al.*¹ have proposed a pole position and rotation angle to describe the opening of the East African Rift Valleys. On the basis of this rotation, they expect extensions of about 30 km in Kenya and 65 km in northern Ethiopia to have taken place. It follows that the mean relative motion of the two plates in Kenya should have been in a direction of 124° east of north. Interpretation of the gravity anomalies from the Kenya Rift provides some confirmation of the hypothesis.

Over the floor of much of the rift valley in Kenya there is an axial, positive Bouguer anomaly²⁻⁵. I have made a detailed interpretation (ref. 5 and unpublished) of this positive anomaly between 0.5° N and 1.5° S. Calculation suggests that the anomaly is caused by dense intrusions beneath the rift floor, presumably of material derived from the upper mantle, which have filled the gap between the separating continental blocks. The total calculated width of these intrusions is between 16 km and 28 km, depending on the assumed density contrast and its variation with depth. If the intrusions represented the total extension, between 2 km and 14 km of the expected extension would be unaccounted for. An additional extension of about 5 km could, however, be taken up by normal faulting⁶. Consequently, the amount of extension inferred from the gravity anomalies is in agreement with that predicted from plate tectonics.

It is also possible to deduce from the gravity anomalies the approximate direction of the relative motion vector. In southern Kenya, the rift follows an S-shaped course: from 2° N to 0.5° N, and south of 1.0° S, its trend is approximately 20° east of north; between 0.5° N and 1.0° S, the trend is about 20° west of north. It is assumed that over this small area the Earth's surface can be considered flat, and that the direction of relative motion is constant (the rotation angle is only 1.9° , so this is approximately true). When a flat plate is broken along an irregular line (the rift) and the two parts are separated without rotation, the amount of separation measured at any point perpendicular to the rift direction varies as the sine of the angle between the local rift direction and the relative motion vector. Because the relative motion across the Kenya Rift near the equator is expected to be approximately 124° east of north, those sections of the rift which trend east of north should show greater extension than those trending west of north. The positive Bouguer anomaly is indeed wider in the NNE-trending sections of the rift, and a quantitative study of the variation of the width of the inferred intrusions with changes of direction of the rift suggests that the direction of relative motion is about 120° east of north. This is in good agreement with the direction of the small circles about the proposed rotation pole; however, considering the inherent ambiguity of any gravity interpretation, and the probability that all of the extension is not taken up by intrusion, this result should be viewed with caution.

Finally, it is known that there are positive Bouguer anomalies over the floor of the main Ethiopian Rift⁷, but at present there are insufficient data to enable the amount of extension to be estimated. A detailed gravity survey of this area is now being made by the Geophysical Observatory in Addis Ababa, and it is hoped that the results

will enable the extension in the Ethiopian Rift to be determined.

The Great Glen Fault in the Shetland Area

THE Bouger anomaly map of the continental shelf to the west of Orkney and Shetland recently published by Bott and Watts¹ provides gratifying confirmation of the geology of this area which I proposed earlier². My predictions were based on an interpretation of the aeromagnetic map of the area and include not only most of the deep sedimentary basins proposed by Bott and Watts but also the great NW-SE trending strip of Lewisian rocks labelled *A* by Bott and Watts.

The chief difference between the gravity map¹ and my interpretation map based on the aeromagnetic map of the area concerns this anomaly *A*. On the gravity map anomaly *A* continues across the north of Shetland to about 0° 40' W. The equivalent feature on the aeromagnetic map ends to the east of 1° 00' W.

After consideration of both the geological evidence and of the aeromagnetic map I correlated the Great Glen fault with a very powerful fault of transcurrent type exposed in Shetland and called the Walls Boundary fault. In conformity with the pattern of the aeromagnetic map I extended the Walls Boundary fault north of Shetland along a line striking only slightly east of north. This extrapolation takes it through part of Bott and Watt's anomaly *A*. Because their anomaly is not displaced along this line they suggest that the Great Glen fault must pass to the east of Shetland and not through it.

This suggestion completely ignores the known geology of the area; it fails to take the Walls Boundary fault into account. This fault has all the hall-marks of a great transcurrent fault. It must continue to the south and north of Shetland for considerable distances. There is nothing on the aeromagnetic and gravity maps to set a limit to the extension of the Walls Boundary fault to the south. On both maps the line of best fit for it is a smooth curve from Shetland to Inverness passing close to the west of Fair Isle.

The extrapolation of the Walls Boundary fault to the north of Shetland can be made with less certainty. The line which best fits both the gravity and the aeromagnetic maps lies to the east of my original line². It passes through 1° 00' W and 61° 00' N and skirts the eastern end of gravity anomaly *A*.

With this projected line for the fault the nearly N-S strike of the fault in Shetland becomes a local deflexion of strike from the general NNE strike to the north and south of Shetland. The change from concave west to concave east can be seen in Shetland, where the fault is

intermittently exposed over 59 km. For 31 km after it enters Shetland from the south the fault has a strike of 004°. For 28 km before it leaves Shetland to the north the strike is 011°. The maximum strike necessary to carry it past anomaly *A* is 020°.

This configuration for the fault in the Shetland area has the advantage that the Nesting fault (a 16 km displacement transcurrent fault (2)) and other major parallel faults in Shetland become the *en echelon* branches which would be expected if such a deflexion of strike took place.

I maintain that Bott and Watts's gravity map not only confirms the presence of the deep sedimentary basins and crystalline gneiss ridges on the shelf to the west of Shetland which I predicted² but also provides additional evidence of the connexion between the Walls Boundary fault and the Great Glen faults and shows that to the north of Shetland the fault resumes the strike it had to the south of Shetland.

DEREK FLINN

Received January 28, 1970.

¹ Bott, M. H. P., and Watts, A. B., *Nature*, **225**, 265 (1970).

² Flinn, D., *Geol. J.*, **6**, 279 (1969).

WE apologize to Dr Flinn for any disquiet we may have caused by omitting to refer to his recent paper¹. We agree with him that the aeromagnetic map² distinguishes regions of shallow and deep magnetic basement by the smoothness of the contours. We disagree, however, with his use of the general anomaly level as an indication of sediment thickness, which is the distinction between his pattern *A* anomalies which "probably overlie deep sedimentary basins" and pattern *B* which "covers sedimentary basins less deep than those of pattern *A*". The usual geophysical approach is to estimate the depth to the basement using well established quantitative techniques³. One of the main points of our report⁴ was to present evidence for three deep Mesozoic basins marked *C*, *D* and *E* on our map. These basins are not delineated in Flinn's interpretation, although they do occur within wider tracts which he interprets as sediment covered.

Flinn has suggested a new line for the Great Glen fault which does not cross gravity "high" *A* north of the Shetlands. This raises a problem which needs to be recognized.

To quote Allen⁵, "probably the most impressive feature of thoroughgoing transcurrent faults is their extreme linearity over literally hundreds of kilometres". Large transcurrent faults should now be interpreted as transform faults which play an essential part in the scheme of global tectonics as boundaries between plates of lithosphere moving laterally relative to each other⁶. If there is no significant internal deformation within the plates, the fault plane must lie on a small circle with reference to the pole of rotation about which the relative motion can be described. The trace of the fault plane can only deviate from a small circle if either one or both of the plates suffer internal deformation during the movement, or if the fault plane has been horizontally displaced at a later stage. Thus Benioff⁷ interpreted the bend in the San Andreas fault in terms of sinistral movement on the Garlock fault which started to develop later than the San Andreas, accompanied by severe distortion where they intersect. The bends of the Alpine fault of New Zealand⁸ can be interpreted in terms of splaying of the fault and deformation currently occurring near the bends.

The new line of Flinn involves changes in direction of the fault south and north of the Shetlands. The bend to the north is particularly sharp. Flinn's line would be acceptable if it could be demonstrated that the required

contemporaneous or later deformation had occurred in the vicinity of the postulated bends. Such deformation might possibly fit into the late Caledonian movements. This problem would be more acute for significant Tertiary (or even post-Devonian) crustal shortening or extension affecting north Britain. The known Tertiary movement is predominantly relatively minor regional extension involved in dyke injection, basin formation and normal faulting.

Collette^{9,10} has presented further evidence to suggest that the line of the Great Glen fault lies east of the Shetland Isles. It is clear that all hypotheses give rise to problems and this should encourage us to look for further evidence particularly in the vicinity of the postulated bends. Perhaps the simplest is the hypothesis advanced by Pitcher¹¹ that the Walls Boundary fault is a splay of the main fault. The main fault would then pass east of the Shetlands.

Structure Determination by the Combination of Anomalous Scattering and Direct Methods

PHASE determination by direct methods is more difficult for non-centrosymmetric than for centrosymmetric crystals. The phase, $\alpha(h,k,l)$, can take any value for the former crystal between 0 and 2π while the choice for the latter crystal is limited to two values, 0 or π . If the structure is non-centrosymmetric and contains a small number of atoms which scatter anomalously, then $\alpha(h,k,l)$ can be determined from the Bijvoet difference, for example, $\Delta I = |F(h,k,l)|^2 - |F(\bar{h},\bar{k},\bar{l})|^2$, and the known phase α'_p of the anomalous scatterers^{1,2}. From

$$\alpha'_N = \alpha'_p + \pi/2 \pm \theta \quad (1)$$

and

$$\cos \theta = \frac{\Delta I}{4 |F'_N| |F'_P|} \quad (2)$$

where α'_N is $\alpha(h,k,l)$, the phase of the reflexion, F'_N , if there were no anomalous scattering. F'_P is the contribution from the absorption term $\Delta f'_P$. The indeterminacy in equation (1) arises because the cosine is an even function. In practice, the ambiguity has been resolved by choosing α'_N to be the phase closest to α'_p (ref. 3) or by calculating a double phased synthesis². An alternative, indeed the original method, is to calculate the Patterson sine function⁴.

A different approach⁵ is to recognize that the incorporation of anomalous scattering data reduces the problem to the comparative simplicity of the centrosymmetric case, or to a choice between two phases, and then to use direct methods to select the observed phase closest to the

correct value. An important difference is that the two possible phases α_1 and α_2 need no longer be π apart.

When $|\cos \theta|_{\text{obs}} \geq 1$ then $\alpha_1 = \alpha_2$ and the phase is known unambiguously. Such reflexions form a basic set from which the phase determination may proceed. For L(+)-lysine hydrochloride dihydrate, using Raman's³ data, fifty-two out of 128 phases can be determined unambiguously in this way. Similarly, from the neutron diffraction data for cadmium nitrate tetradeuterate⁶, thirty-two out of 161 phases can be determined.

From the basic set, there are two possible ways of proceeding. Phases for the remaining reflexions can be calculated and the observed phase closest to the calculated phase can be chosen or, alternatively, phases can be determined and refined without paying further attention to the observed phases. A reasonable approach would be to carry out sufficient cycles of the first alternative to determine as many phases as required, and then to refine them by the second method, because the observed phases will be liable to error. A preliminary cycle in which the basic set alone is refined should be performed because α_1 for the set may have only a small number of discrete values depending on the space group and the number of anomalous scatterers in the asymmetric unit. For example, for lysine hydrochloride, the phases of the basic set were 90° or 270° . It should be noted that no arbitrary origin-defining phases can be used because the origin is already determined when placing the anomalous scatterers.

The method described here could be useful for determining the structures of large molecules of biological interest which are often solved by combining multiple isomorphous replacement with anomalous scattering data. An obvious advantage would be in the reduction of the number of data to be collected.

Supralinearity of Thermoluminescent Phosphor Lithium Fluoride

THE non-linear response to dose reported for many thermoluminescent phosphors^{1,2} has caused serious concern both for dosimetry and for dating techniques.

We have investigated square samples of TLD-100 phosphor 3 mm across and 1 mm thick. The thermoluminescence output induced by a ⁹⁰Sr source was measured conventionally with a photomultiplier tube in oxygen-free nitrogen and a heating rate of 20°C/s . A dose of a few kilorads was given to the phosphor and the TL output was measured. In addition to the peaks reported by Zimmerman *et al.*³, a tail was observed at the higher temperature region. A detailed study on this tail showed that there are at least two peaks in its fine structure. These two peaks were found to increase with dose to saturation at near 3 megarads. The peak positions are at 370°C and 430°C respectively. The structure of this tail and its dependence on dose can be seen from Figs. 1 and 2.

A thermal annealing experiment was performed in order to study the characteristics of these peaks. Both peaks were found to tail off exponentially at constant

temperature. The dependence on annealing temperature of the half-lives of both peaks was found to be the same as for the peaks reported by Zimmerman *et al.*³ With the same annealing technique, however, the *s* factors and the energy depths of the two peaks were found not to fit the model of Randall and Wilkins⁴. These facts suggested that the peaks are not related to the electron trapping centres. An optical absorption measurement on an irradiated phosphor showed that the two peaks are related to the absorption V-centre of 250 nm, which is also present in a virgin TLD-100 phosphor but in smaller amounts. Heating the phosphor up to 300° C and then rapidly quenching to room temperature can remove the absorption F-centre of 444 nm completely, but the V-absorption peak is only reduced by a small factor. It was also found that the position of this V-absorption peak shifted to a shorter wavelength region on quenching at a higher temperature. This coincided with the shift of the two peaks to a position equivalent to a higher quenching temperature on annealing at a higher temperature or with longer annealing time at constant annealing temperature. The absorption spectrum of an irradiated phosphor and the change due to different quenching temperatures are shown in Fig. 3.

The height and area of these two peaks were found to increase linearly with dose in the region of a few kilorads. The striking fact is that, by extrapolating to zero glow, there is a threshold dose for producing these

Fig. 1. Thermoluminescent glow of TLD-100 phosphor induced by a dose of 30 krad (⁹⁰Sr source).

Fig. 2. Thermoluminescent glow against β radiation dose for TLD-100. A, 370° C + 430° C peak area; B, individual peak height.

Fig. 3. Optical absorption spectrum of an irradiated TLD-100 phosphor (5.4 Mrad) for different quenching temperatures.

peaks by radiation. The threshold dose was found to be 1 kilorad, which coincides with the dose at which supralinearity is reported to begin in TLD-100 phosphor⁶. When the phosphor was exposed to a high dose of a few hundred kilorads we can see that the 2nd, 4th and 5th peaks reported by Zimmerman are all saturated, but the 3rd peak is still increasing with the two high temperature peaks. This fact suggests that extra light should be expected as more recombination centres are available.

If we assume that the supralinearity of LiF phosphor is due to the extra recombination centres produced by high energy particles, then the supralinearity should depend inversely on the linear energy transfer (LET) of the radiation. This agrees with the findings of other workers^{2,5}. This hypothesis can also explain why a phosphor is sensitized when annealed at 280° C for one hour after irradiation with 10⁵ rads gamma ray (⁶⁰Co) (ref. 6), simply because the lifetime of these centres at 280° C is much longer than one hour (the value of the 430° C peak by extrapolation is $T_{1/2} = 6$ hours). I hope to publish a fuller report of these experiments in due course.

Relativistic Behaviour of Moving Terrestrial Clocks

EINSTEIN concluded in his 1905 paper on relativity that "a balance-clock at the equator must go more slowly, by a very small amount, than a precisely similar clock situated at one of the poles under otherwise identical conditions"¹. At that time, of course, he had not yet developed the general theory and did not realize that the difference in the gravitational potential at the equator and poles would just cancel the time dilatation from the difference in surface speeds, as has been pointed out recently by W. J. Cocke². Cocke has also shown that, in so far as the Earth assumes the shape of the geoid (and weak tidal fields can be neglected), its entire surface is an "equal time" surface. There remains an interesting question, however: What would be the rate of a standard clock that is moving

relative to stationary standard clocks on the geoid? The standard answer that moving clocks run slow by the well known factor $(1 - v^2/c^2)^{1/2}$ is almost certainly incorrect. The purpose of this note is to discuss this question of the rate of moving terrestrial clocks relative to stationary ones.

According to relativity theory, a clock records proper time. We are interested in finding the proper time for a body that is moving in a time-independent, permanent gravitational field. The notation and terminology of Møller³ will be used. According to Møller (Chapter VIII, equation 99), the rate of a moving standard clock in a gravitational field is given by

$$d\tau = dt(1 + 2\chi/c^2 - u^2/c^2)^{1/2}$$

where τ is the proper time, χ is the scalar gravitational potential, and u is the speed relative to a coordinate system in which t is the coordinate time. We are concerned with a weak gravitational field ($\chi \ll c^2$) and slow speeds ($u^2 \ll c^2$), so the approximation

$$d\tau \approx (1 + \chi/c^2 - u^2/2c^2)dt \quad (1)$$

will be adequate.

Let us consider a special case which is easy to visualize and can be generalized if desired. Consider an airborne clock at an altitude h directly above the equator and moving with a ground speed v , either directly East ($v > 0$) or directly West ($v < 0$). Relative to a non-rotating reference system, the speed of this clock is $u = v + (R+h)\Omega$, where Ω is the Earth's angular velocity and R is its radius. The scalar gravitational potential at the airborne clock is $\chi = -GM/(R+h)$, where G is the gravity constant and M is the Earth's mass. The speed of a ground based reference clock is $u_0 = R\Omega$, however, and its scalar potential is $\chi_0 = -GM/R$. Hence, applying equation 1 to the airborne clock gives

$$d\tau = [1 - GM/c^2 R(1 + h/R) - (R\Omega(1 + h/R) + v)^2/2c^2]dt$$

and to the ground based clock gives

$$d\tau_0 = [1 - GM/c^2 R - R^2\Omega^2/2c^2]dt$$

These equations give the time intervals of the respective clocks relative to an imaginary background system of coordinate clocks. But only proper time is recorded by real clocks; the coordinate time is not recorded. The unknown coordinate time can be eliminated, however, by taking the ratio $d\tau/d\tau_0$. Assuming $h \ll R$ and expanding to lowest order in all terms, a little algebra gives

$$d\tau/d\tau_0 = 1 + gh/c^2 - (2R\Omega v + v^2)/2c^2 \quad (2)$$

where $g = GM/R^2 - R\Omega^2$, the measured surface value of the acceleration of gravity at the equator. Equation (2) is remarkable in that it predicts that an airborne clock may run fast or slow relative to a ground based reference clock, depending on the sign of v . This directional dependence reflects the prediction of relativity theory that the relative rate of two clocks does not depend solely on the relative speed when both clocks experience acceleration. Moreover, aircraft ground speeds these days are great enough so that this directional dependence should be appreciable with modern, portable atomic clocks.

For example, suppose a jet plane carrying a portable atomic clock were to circumnavigate the globe once at the equator while flying at an altitude of 10 km (33,000 feet), with a ground speed of 300 m/s (670 miles/hour). Equation (2) predicts that, relative to an identical reference clock kept at the home port, the airborne clock would lose about 130 ns after an eastward circumnavigation, but would gain about 290 ns after a westward circumnavigation. These time offsets, particularly because they are positive for one direction and negative for the other, should be perceptible above the inherent drift of modern atomic clocks. The hydrogen maser clock is said to have an inherent drift of less than 1 part in 10^{14} (ref. 4). An experiment such as this one might empirically resolve once and for all the long-standing debate on the clock paradox⁵.

Finally, when time standards of the world's laboratories are intercompared by transporting portable standards between them⁶, any relativistic time corrections arising from interlaboratory transit would need to take into account the directional effects discussed here.

BIOLOGICAL SCIENCES

Amino-acid Sequence of the Q β Coat Protein

THE RNA phages provide an excellent system in which to determine the primary structure of a messenger RNA and relate this to the proteins which it codes^{1,2}. By establishing the frame of reading, it is then possible to locate initiation and termination sites as well as extragenic regions^{3,4}. Our previous work concerned the amino-acid sequences of the f2 and R17 coat proteins^{5,6}. Using R17 it was possible to identify the initiation region corresponding to the coat protein cistron⁷; the termination region corresponding to the carboxy-terminus of the same cistron⁴; and an internal region of 57 nucleotides out of this cistron corresponding to residues 81-99 of the coat protein³.

The oligonucleotides, from R17 which have been sequenced were obtained by enzymatic fragmentation^{3,4}. With Q β , it proved possible to purify a specific replicase which could then be used to achieve partial synthesis of the RNA *in vitro*⁸. Analysis of the RNA pulse labelled *in vitro* has established the sequence of the first 175 nucleotides from the 5' end⁹. To relate the nucleotide and amino-acid sequences of Q β , we have analysed the structure of the Q β coat: the protein coded by Q β RNA that can be most readily obtained. Here we compare its sequence with that of the coat protein of the antigenically unrelated bacteriophage f2 and relate it to the nucleotide sequences already obtained from Q β RNA.

Stepwise Edman degradation performed on the coat protein revealed the sequence Ala-Lys-Leu-. One carboxy-terminal tyrosine residue (per molecular weight 14,000) was found by digestion with carboxypeptidase A. A tryptic digest of the performic acid oxidized protein was separated by ion exchange chromatography on 'AG 50-X4' resin and by gel filtration. The purity of the peptides was checked by paper electrophoresis and chromatography. Sequences in the smaller peptides were established by Edman degradation, digestion with leucine aminopeptidase and carboxypeptidase A and B⁹. The location of amides was in some instances inferred from enzymatic digestion and the electrophoretic mobilities¹⁰. Larger peptides were subjected to enzymatic fragmentation by chymotrypsin and subtilisin, and the resulting peptides were sequenced as described. The sum of the amino-acids from all tryptic peptides is in good agreement with the amino-acid composition of the Q β coat protein. Digestion

Fig. 1. Amino-acid sequence of Q β coat protein. The location of enzymatic splits used to establish the sequence is shown by arrows: T, trypsin; Th, thermolysin; C, chymotrypsin. The sequence of the f2 coat protein 5 has been provisionally aligned with that of the Q β protein to maximize the number of identical residues (see text). The numbers under each residue represent the minimum number of base changes per codon necessary to account for the amino-acid interchanges at each position in the f2 and Q β coat proteins.

of the intact protein by chymotrypsin, thermolysin and streptococcal proteinase gave overlap peptides which led to the arrangement of the tryptic peptides as shown in Fig. 1 and thus provided evidence for a linear structure for the Q β coat protein.

In the oligonucleotide fragment isolated from Q β RNA by Hindley and Staples¹¹, the five RNA triplets following the AUG codon code for amino-acids which are identical to those we have determined for the amino terminal sequence of the coat protein. Taken together with the finding of a peptide from an *in vitro* protein synthesizing system programmed by Q β RNA (unpublished results of M. Osborn, K. W. and H. Lodish) having the same amino-acid sequence but containing an amino-terminal formyl-methionine residue, these results establish that the RNA fragment of Hindley and Staples¹¹ contains the coat initiation region.

Knowledge of the coat protein sequence can confirm that the known 5'-terminal nucleotide sequence⁸ could not contain this initiation region. If the method of Billeter *et al.* can be extended to the nucleotide sequence beginning in the region 800-1600, where the coat protein cistron is expected⁸, it will be possible to compare directly the corresponding amino-acid and nucleotide sequences; otherwise, this comparison could be made by the methods successfully used in the case of R17 RNA³.

The coat protein of Q β bacteriophage is distinct from the corresponding f2 and R17 proteins in lacking the three amino-acids methionine, tryptophan and histidine. Like the f2 and R17 sequences^{5,6}, the Q β coat protein has intermittent stretches—up to twelve amino-acids—of non-polar residues. Although the Q β coat protein is only two residues longer than the f2 coat protein, it has eight more acidic and basic residues. In spite of these differ-

ences, however, the two proteins probably fold similarly to form the virus capsid. When the f2 and Q β sequences are aligned starting at the amino-terminus, sixteen out of 129 residues are identical and 46 (36 per cent) can be accounted for by single base changes. The percentage of residue interchanges that can be accommodated by alteration of a single base is within the range expected by comparison of random sequences¹². If the two proteins are aligned so that the carboxy-terminal residues coincide, eighteen of the residues are identical and 50 (39 per cent) can be accounted for by single base changes. A greater degree of homology is achieved, however, if insertions and deletions are allowed (Fig. 1). Thus insertions of Gly at position 25, Val at 41, Thr at 74, Cys at 79, Asp at 80, and deletions between 56-57, 59-60, 65-66 and 106-107 permit the alignment of residues 30-34, 48-52 (allowing for a Val for Cys replacement), 57-59 and 62-65 (allowing for a Gln to Glu substitution), using the Q β numbering system. In this way thirty residues occupy identical positions, and 62 (48 per cent) can be accounted for by single base changes. Although certain regions seem to be conserved, there is no evidence for any restriction in the rest of the protein. This, however, is only a provisional comparison, and other alignments might well allow a greater degree of homology.

The mutational events necessary to account for this situation are well accepted for DNA coded proteins, but they have not yet been established for phages with RNA as the genetic information. It may be that in aligning these coat protein sequences we are comparing the end products of a convergent evolutionary process and that the identities observed are fortuitous. Examination of a coat protein from the third class of RNA phages may clarify this matter.

Certain regions in both proteins that resemble each other chemically include the carboxy-terminal section from the residues 116–131 which is devoid of basic and aromatic residues, and the region from residues 42–65, in which three stretches of contiguous residues can be aligned so that the f2 and Q β sequences are identical. A similar correspondence is found between f2 and the antigenically distinguishable¹³ but related fr coat protein¹⁴. Although the f2 and Q β coat proteins both contain two cysteine residues with free SH groups, the cysteines occupy different positions in the two proteins. Functionally they are probably not important, for the coat protein from GR and SD (which comprise a third group of antigenically unrelated RNA phages¹⁵) is entirely devoid of cysteine. Clearly, a knowledge of invariant regions in the coat proteins would help in delineating the requirements for capsid formation and other functions in which the coat protein is presumably involved, such as regulation of the translation of the replicase cistron^{16,19}, stimulation of the rate of coat protein synthesis²⁰ and lysis of the host cell²¹. Sequence data on proteins in the cysteine deficient class must be obtained, however, before even tentative interpretation of structure-function or evolutionary relationships can have any validity.

This work was supported by a US Public Health Service research grant. We thank Drs Charles Weissmann and Peter Gilham for a gift of Q β coat protein. J. K. is a fellow of the Jane Coffin Childs Memorial Fund.

of this class in this strain. C57Bl/6 mice whose γG_{2a} molecules express the *Ig-1b* locus can produce antibodies reacting with *Ig-1a* determinants, if they are injected with 5563 myeloma protein in a suitably immunogenic form; but CBA mice cannot. The *Ig-1* locus is expressed on the constant region within the Fc fragment¹. It has been found that mice producing antibodies against these determinants also produce antibodies against idiotype—myeloma specific—determinants located within the Fab fragment². Mice immunized with non-conjugated myeloma protein either produce antibodies against both allotypic and idiotype specificities or they produce nothing against either determinant. Thus mice cannot detect idiotype determinants on non-conjugated myeloma protein with allotypic determinants that their own immunoglobulins possess. Cohn *et al.*³ have suggested that the Fc portion of the molecule acts as a “carrier” for the Fab portion, in the sense that an otherwise non-immunogenic determinant (the “hapten”) becomes immunogenic if attached to a structure which is itself immunogenic (the “carrier”). It has been shown that the “carrier effect” of Ovary and Benacerraf⁴ increases the immune response to the “hapten equivalent” by virtue of antigen-mediated cell cooperation^{5,6}.

To test the hypothesis that an antigenic determinant on the Fc acts as a carrier for determinants on the Fab, 2,4-dinitrophenol (DNP) was conjugated to 5563 myeloma protein and this alum-precipitated conjugate, with *Bordetella pertussis* as adjuvant, was injected into CBA mice. The unaltered Fc portion of the molecule could not act as the carrier for the reasons stated. But in these experimental conditions the 5563 protein has a DNP determinant to act as the “carrier”.

The immunological response to an antigenic determinant is increased if the host is presensitized to the carrier⁴. This presensitization engenders a population of helper cells, specific for the carrier, which are thought to be thymus-derived. Painting of the skin, with 1-fluoro-2,4-dinitrobenzene (FDNB), leads to cell-mediated immunity specific for DNP, which is almost certainly mediated by thymus-derived cells. Accordingly the mice were skin painted with FDNB to provide them with a population of thymus-derived, DNP-specific helper cells.

Protein from myeloma 5563 was extracted from the solid tumour by homogenization in 0.25 M sucrose containing 0.004 M MgCl₂ followed by centrifugation at 2,000g. The protein in the supernatant was further purified by precipitation in 50 per cent saturated ammonium sulphate and finally by ion exchange chromatography on DEAE-cellulose (Whatman DE-32) in 0.01 M Tris buffer (pH 8.1)–0.05 M NaCl. DNP-5563 conjugate was prepared by gently stirring the protein in 0.5 M sodium bicarbonate with FDNB for 1 h at room temperature, followed by dialysis. The molar ratio of DNP to 5563 protein, determined spectrophotometrically, was 3.2 : 1. Fab and Fc fragments were prepared by papain digestion followed by ion exchange chromatography.

CBA mice, 2–3 months old, were presensitized to DNP by painting their shaved abdomens with 50 μ l. of 0.5 per cent FDNB in a 1 : 1 mixture of olive oil and acetone. Ten days later the mice were injected with either 0, 25, 50, 75 or 100 μ g of alum precipitated DNP-5563 plus 2×10^9 formalin-killed *B. pertussis* organisms (kindly provided by Dr J. Cameron of Burroughs Wellcome Ltd). After three weeks, all the animals were boosted with 100 μ g of DNP-5563 in saline, and 10 days later the mice were bled. The anti-idiotypic antibody content of the individual sera was measured by means of a co-precipitation assay.

Each serum was tested at four dilutions. Ten μ l. of 10^{-8} I-5563 Fab (6×10^{-8} M) was added to 50 μ l. of antiserum diluted in 1 : 24 normal mouse serum diluted in borate buffer⁷. The antigen-serum mixture was incubated for 30 min at room temperature; then 50 μ l. of rabbit anti-mouse immunoglobulin serum was added to each tube,

Ability of CBA Mice to produce Anti-idiotypic Sera to 5563 Myeloma Protein

MICE can produce isoantibodies against immunoglobulins which carry allotypic determinants not present on their own immunoglobulin. For instance, the plasmacytoma 5563 (a γG_{2a} protein) arose spontaneously in C3H mice and expresses the *Ig-1a* locus like normal immunoglobulin

the contents of which were thoroughly mixed before being incubated for 30 min at 4° C. It is clear that the rabbit anti-mouse immunoglobulin serum cannot have any specificity for 5563 Fab. This was ensured by absorbing the serum with normal mouse immunoglobulin Fab made insoluble by conjugation to 'Sephadex', the absorption being repeated until no precipitation of ^{125}I -5563 Fab was obtainable. After incubation, the tubes were then centrifuged at 2,000g for 30 min. The supernatant was removed and the radioactivity of the precipitate measured in a scintillation counter. The \log_2 of the dilution of antisera that would bind 50 per cent of the radioactive 5563 Fab was calculated.

The anti-5563 idiotype antibody response was dependent on the amount of alum-precipitated antigen used (Fig. 1). In those animals which were boosted but had received no alum-precipitated antigen, little or no serum antibody could be detected. The animals which received the most alum-precipitated antigen produced the most antibody. The response between these two extremes was linear.

Another set of mice were treated as described, but they were not painted with FDNB. Instead, they were injected with alum-precipitated DNP-5563, plus *B. pertussis*, and were boosted with DNP-5563 in saline. There was no detectable anti-5563 Fab antibody in the sera of any of these mice.

Only 5563-Fab inhibits the binding of radioactive 5563-Fab by CBA anti-5563 (Fig. 2). The immunoglobulin, and immunoglobulin fragments which did not inhibit specific binding, included (1) immunoglobulins with the same class-specific and allotypic determinants—for example, 5563-Fc and LCP-1 protein; (2) immunoglobulins with different class and therefore different allotypic determinants—for instance, MCP-25 and MOPC-104G proteins; (3) immunoglobulins with the same L-chain type (K)—for instance, LPC-1 and MPC-25 proteins; and (4) an immunoglobulin with a different L-chain type (λ)—MOPC-104C protein. The constant region of all mouse L-chains of the same type tested so far has been shown to have the same amino-acid sequence. Furthermore, it has been shown that mouse myeloma proteins of the same class and allotype differ in their H-chain amino-acid sequence only in the N-terminal variable region. The antigenic determinants detected are therefore peculiar to 5563-Fab, and are therefore idiotype.

CBA mice, which do not in normal circumstances respond to an injection of alum-precipitated 5563 mye-

Fig. 1. Antigen dose response. The abscissa represents the amount of alum-precipitated DNP 5563 used to prime CBA mice which had been skin painted with 0.5 per cent FDNB 10 days previously. All mice received 100 µg of DNP 5563 in saline 3 weeks later. The ordinate represents the \log_2 of the dilution of antisera that would bind 50 per cent of the radioactive 5563 Fab at a final concentration of 10^{-8} M. Each point represents the mean of the individual values of six mice. The vertical bars represent the standard error for each group of six mice.

Fig. 2. Inhibition, by various myeloma immunoglobulins, of the binding between CBA anti-5563 and labelled 5563 Fab. Ten µl. of various concentrations of inhibitor was added to 50 µl. of a dilution of anti-serum that would bind 80-90 per cent of the radioactive 5563 Fab. After thorough mixing, 10 µl. of ^{125}I -5563-Fab (6×10^{-8} M) was added. The contents of the tube were mixed and then incubated for 30 min at 20° C, after which 50 µl. of rabbit anti-mouse immunoglobulin was added. Mixing was followed by incubation for 30 min at 4° C, and centrifugation at 2,000g for 30 min, removal of the supernatant and measurement of the radioactivity in the precipitate. The degree of inhibition was calculated as a percentage of the amount of label precipitated in controls without inhibitor. The various purified myeloma immunoglobulins tested are: 5563 Fab, \square ; 5563 Fc, \circ ; LCP-1 (γG_{2a} Ig-1a), \blacktriangledown ; MCP-25 (γG_1 Ig-4a), ∇ ; MOPC-104 (γM), \blacksquare .

loma protein plus *B. pertussis*, could be made to do so by adding a DNP determinant to the myeloma protein, and presensitizing the mice to DNP. These mice must have possessed antibody forming cells and their precursors with receptors for this idiotype determinant. All that seems to be required for the response was that the immunogen should be presented in an appropriate way to these cells. The observation that the animals have to be presensitized to this new determinant supports the argument that the conjugation has not non-specifically increased the immunogenicity of the 5563 molecule. The activating effect of skin painting with FDNB supports the hypothesis that the DNP group is acting in the role of the "carrier", as proposed by Mitchison and Rajewsky^{5,6} (see also ref. 8). According to this hypothesis the DNP-specific helper cells present the idiotype determinant to antibody forming cell precursors.

I thank Drs N. A. Mitchison and M. C. Raff for their help.

Immunological Paralysis induced by an Idiotype Antigen

A DIRECT association presumably exists between idiotype specificity and the structure of the antibody site. The level of a particular idiotype should therefore vary in normal individuals and could reach relatively high levels after prolonged immunization with a homogeneous

antigen. There must therefore be a mechanism which prevents autoimmunization by idiotypes. Two such mechanisms which have been suggested are (1) that an animal is tolerant of (paralysed by) its own idiotype determinants¹, and (2) that an antigen can only be an immunogen when it carries two widely separated determinants which enable it to participate by means of a carrier-effect mechanism²⁻⁴, in a cooperative act between two kinds of cell involved in the immune response⁵. Hypothesis (2) is contradicted by the results described in the previous article⁶, where the dinitrophenyl derivative of myeloma protein 5563 (DNP-5563) failed to elicit an immune response without previous or concomitant immunization against the DNP group, and also by the known capacity of multideterminant antigens such as mammalian γ -globulins to induce paralysis rather than immunity in adult animals.

Extrapolation from experiments with bovine (BGG) and other γ -globulins in CBA mice (see ref. 7) suggests that 2 μ g of 5563-myeloma protein would be insufficient to induce a state of immunological paralysis, whereas 100 μ g or more would be enough. The experiments with BGG showed that the state of paralysis was acquired by a CBA mouse progressively over a period of up to 3 weeks after the injection of the paralytogen. Unpublished findings of G. M. I. have shown that the level of 5563-idiotype (expressed in terms of γ -globulin bearing this determinant) in four inbred strains of mice is about 35 ng/ml. of serum. We have concluded from this observation that a state of immunological paralysis is unlikely to exist for the 5563-idiotype. The observation of several workers that various anti-idiotype antibodies can be raised experimentally (see ref. 6) strongly supports this view. Consequently we decided to find out if 5563-myeloma protein was capable of inducing a state of immunological paralysis to its idiotype determinant in adult CBA mice.

Male CBA mice, aged 3-5 months, were used. Myeloma protein 5563 was prepared from solid tumour as described⁶. Purified 5563-protein which was to be tested for its properties as a paralytogen was dialysed against physiological saline and then centrifuged at 30,000*g* before being injected intraperitoneally. The half-life of 5563-protein in the blood of CBA mice was measured as described pre-

Fig. 1. The anti-5563 idiotypic response in CBA mice challenged with different amounts of antigen. Each point represents the mean titre (ref. 6) in six experimental animals. ■, Controls; ▼, mice injected with 0.5 μ g particle free 5563-protein 4 h before challenge; □, mice injected with 100 μ g of 5563-protein 28 days before challenge. Vertical bars represent one standard deviation.

Fig. 2. Similar to Fig. 1 except that mice were injected with 1.4 μ g of 5563-protein 4 h before challenge (▼) and with 320 μ g of 5563-protein 28 days before challenge (□).

viously⁸, using ¹³¹I-labelled protein prepared by the ICI method of McFarlane⁹. Experimental and control mice were tested for their ability to make anti-5563 myeloma-specific antibodies (anti-idiotype) by the method of Iverson⁶.

A group of CBA mice were injected intraperitoneally with 100 μ g of particle-free 5563-protein (another group received 320 μ g). Twenty-eight days later all these mice, together with controls, were skin painted with 0.05 ml. of a 1:1 mixture of acetone and olive oil containing 0.5 per cent fluorodinitrobenzene (FDNB). After a further 10 days sub-groups from each major group of mice were challenged with 25, 62 or 100 μ g of alum-precipitated DNP-5563-protein conjugate (molar ratio, 3.2:1) together with 20×10^8 *Bordetella pertussis* organisms. The challenging doses used were in a range where it had previously been shown that there was a distinct dose-response relationship between the dose of antigen (idiotype) and the antibody response. Ten days after the challenge, all the mice were boosted by an intraperitoneal injection of 100 μ g of 5563-protein in saline. After a further 10 days the mice were bled individually and the individual sera titrated for their content of anti-idiotype antibody using a co-precipitation assay as described⁶.

One mg of ¹³¹I-5563-protein was injected into five CBA mice, and an estimate was made of the half-life of the protein in the blood: this was 5.4 days. From this rate we calculated that mice injected with 100 μ g and 320 μ g of 5563-protein would have in their extracellular body fluids a total of 0.5 μ g and 1.4 μ g of 5563-protein, respectively, at the time of challenge. This small amount of antigen might interfere with the challenging injection, so we included groups of control mice which were injected with these amounts of 5563-protein 4 h before challenge.

The results (Figs. 1 and 2) show (1) that the amounts of anti-idiotype antibody produced in response to the different challenging doses of antigen correspond to the amounts obtained previously; (2) that 1.4 μ g of 5563-protein injected as a particle-free solution 4 h before challenge had a small effect in lowering the ensuing anti-idiotype response; (3) that 100 μ g or 320 μ g of particle-free 5563-protein, injected a few weeks before challenge, results in a complete suppression of the anti-idiotype response.

If, as might be expected, the idiotypic antigens of normal antibodies behave like the myeloma protein

described here, then the function of paralysis by such antigens may have an important biological function. For example, a single species of antibody—that is, a population of antibody molecules homogeneous in both specificity and affinity—will normally be at concentrations too low for its idiotype to have induced either immunity or paralysis. If, however, the animal is immunized with the appropriate antigen the concentration of idiotype may rise to concentrations where either paralysis or immunity could be induced. It is known that the injection of sufficient amounts of antibody-antigen complex can lead to the production of anti-idiotypic antibody¹. In a situation where such complexes may form naturally it is clearly important that the relevant idiotypic determinants should have been able to induce paralysis readily, if autoimmunity is to be avoided. Conservation of primitive features among the γ -globulins of different mammalian species¹⁰, together with a strong selective pressure favouring the evolution of a mechanism whereby γ -globulin molecules, although antigenic, are non-immunogenic, may offer an explanation of the immunological situation such as that which follows the injection of BGG into mice.

Two Anti-inflammatory Components in Antilymphocytic Serum

ANTILYMPHOCYTIC serum (ALS) is widely known for its ability to impair immunological responsiveness, especially of cell-mediated immunity^{1,2}. The main immunosuppressive component of ALS *in vivo* is IgG (7S- γ) immunoglobulin^{3,4}. Administration of ALS to animals also causes a marked reduction in inflammation, as judged by various experimental models⁵⁻⁷, without causing increased adrenal activity^{5,6}.

In this study anti-guinea-pig lymphocytic serum, as well as anti-rat lymphocytic serum, was shown to have anti-inflammatory activity in the rat. An attempt was therefore made to separate anti-inflammatory components from the immunosuppressive component (IgG, 7S- γ) of antilymphocytic sera using gel-filtration chromatography.

Anti-rat (Wistar strain) lymphocytic serum (ARLS) and anti-guinea-pig (Hartley strain) lymphocytic serum (AGPLS) were raised² separately in New Zealand white rabbits (2–3 kg body weight) by giving two intravenous injections, 14 days apart, of a suspension of 10^9 viable thymocytes in Hanks balanced salt solution. The rabbits were bled 7, 10 and 14 days after the final injection of thymocytes. Complement in the pooled serum was inactivated (heated at 56° C for 30 min), and erythrocyte cytotoxic antibodies were absorbed by addition of 15 per cent packed homologous erythrocytes (37° C for 30 min). The antisera, and normal rabbit serum (NRS) for use as a control, were freeze-dried and stored at –20° C. Before use, freeze-dried products were reconstituted with either sterile distilled water or isotonic saline. ARLS and AGPLS were fractionated as shown in Fig. 1 and their

Fig. 1. Fractionation of the ALS was performed on a column of 'Sephadex G-150' (5 × 100 cm) eluted by upward flow at 50 ml/h with 0.5 M NaCl. Samples of 1.5 g dry weight of the sera (ARLS or AGPLS) were subjected to recycling chromatography using automatic protein fractionation and ultraviolet analysis equipment (LKB). Recycling was started at X and terminated at Y at which stage eluant collection began. The fractions taken for anti-inflammatory testing were: A, macroglobulin fraction (19S); B, IgG (7S- γ) fraction; C, AIF fraction; D, albumin fraction.

immunosuppressive potency was assessed against the skin homograft reaction.

Female Wistar rats (approximately 100–120 g) were recipients for full-thickness tail skin homografts taken from hooded rat donors (groups of eight rats). The graft area on a flank was covered with 'Vaseline'-gauze ('Jelonet', Smith and Nephew) and protected with a light casing of self-adhesive bandage ('Prestoband', Vernon) for 6 days.

The anti-inflammatory activity of both ARLS and AGPLS, or of their chromatographically separated fractions, was determined using carrageenin induced oedema of the rat hind foot^{8,9}. Groups of five Wistar rats (males, 140–180 g) were used for assays. Oedematous inflammation was produced by injection of 0.1 ml. of 1.0 per cent carrageenin (Marine Colloids) in isotonic saline into the plantar aponeurosis of the right hind foot. The ALS material (or NRS) was injected subcutaneously into the interscapular region at the time of injection of carrageenin into the foot. The volume of the foot was measured plethysmographically⁹ before injection of carrageenin and at the height of the inflammatory reaction, 5 h later, anti-inflammatory activity was calculated as the percentage inhibition of paw swelling compared with control groups.

Table 1. EFFECT OF ALS AND NRS ON CARRAGEENIN-INDUCED OEDEMA OF THE RAT HIND FOOT

Treatment (subcutaneous)*	Dose (mg dry wt/kg body wt)	Anti-inflammatory effect (percentage inhibition of oedema formation)	Significance (P) compared with saline treated control
NRS	1,000†	17	N.S.
AGPLS	1,000	48	< 0.001
ARLS	1,000	68	< 0.001

* Freeze-dried materials were reconstituted before injection—control animals received an equivalent volume of sterile isotonic saline.

† 1,000 mg of freeze dried rabbit serum is approximately equivalent to 12.5 ml.

Both ARLS and AGPLS significantly suppressed oedema (Table 1), though ARLS had the greater efficacy. Table 2 shows a representative result for the anti-inflammatory effect of various ALS fractions obtained by 'Sephadex' chromatography (Fig. 1). Whereas ARLS possessed anti-inflammatory activity in the IgG (7S- γ) fraction, AGPLS IgG (7S- γ) did not produce a significant reduction of inflammation in the rat. In both antisera, however, significant additional anti-inflammatory activity was found in the fraction called AIF (non-specific anti-inflammatory factor). These findings may account for the fact that AGPLS had previously been found less effective than ARLS in suppressing inflammation in the rat (Table 1). Because the AIF fraction from both ARLS and AGPLS had anti-inflammatory activity in rats, we concluded that there are two anti-inflammatory components in ALS, namely, IgG (7S- γ) and AIF, but only the former had species specificity. The AIF was probably produced in the animal in which the antisera was raised as a conse-

Table 2. EFFECT OF 'SEPHADEN'-SEPARATED FRACTIONS* OF ALS ON CARRAGEENIN-INDUCED OEDEMA OF THE RAT HIND FOOT

† The dose of chromatographic fractions was equivalent to the original dose (1,000 mg/kg) of whole serum.

Table 3. EFFECT OF 'SEPHADEN' SEPARATED FRACTIONS OF ARLS ON SKIN HOMOGRAFT SURVIVAL IN RATS

Treatment	Dose*	Graft survival (days ± s.d.)
IgG (7S-γ)	200 mg/kg	20.8 ± 4.1
AIF fraction	250 mg/kg	10.7 ± 1.5
Controls	3.5 ml. saline	10.6 ± 1.4

* Administered subcutaneously on days 2 and 5 after grafting (hooded rat recipients; August rat donors of tail-skin grafts). Groups of eight rats were used for assay.

quence of the inflammatory—rather than the immunological humoral—response to foreign lymphocytes.

The results (Table 3) confirm that the IgG (7S-γ) fraction of ARLS is immunosuppressive in that it significantly delays rejection of rat skin homografts, a property not shared by the AIF fraction. It is well known that ALS administration delays or prevents rejection of homografts only in the species of animal against whose lymphocytes the antiserum was raised¹⁰.

Previous experiments have demonstrated the production, during acute inflammation, of an anti-inflammatory protein by a number of mammalian species (man¹¹, rat⁹ and guinea-pig¹²). This anti-inflammatory protein occurs in inflammatory exudate and to a lesser degree in serum, and is probably the same as the AIF of antilymphocytic sera, for it has similar elution characteristics on 'Sephadex' chromatography of cell-free inflammatory exudates^{9,12}. Unlike ALS IgG (7S-γ), the anti-inflammatory protein is not lymphocytotoxic (unpublished finding).

The physiological significance of the anti-inflammatory protein is unknown, but it might play a part in the homeostatic control of inflammation before resolution and repair at the inflammatory site.

Because only certain batches of ALS have anti-inflammatory activity—though still possessing immunosuppressive potency⁷—AIF is either variably produced during the raising of ALS and/or is not present at the particular time of collection of serum. The use of Freund's adjuvant in raising ALS should enhance the formation of AIF, for irritant substances implanted or injected into animals elicit formation of the anti-inflammatory protein^{9,11-13}.

ALS has aroused much interest in clinical medicine as the most powerful immunosuppressive agent known, and it is often chosen for the treatment of rejection crises of foreign organ transplants. It seems likely that transplant patients also produce the anti-inflammatory protein as a consequence of surgical trauma, and introduction of foreign tissues including ALS IgG (7S-γ). Surgery itself, for example, partial gastrectomy¹⁴, results in the formation of the anti-inflammatory protein. It is not yet clear whether the anti-inflammatory substances in ALS potentiate the immunosuppressive activity of ALS IgG (7S-γ). M. E. J. B. is in receipt of an MRC research grant.

Invertebrate Protein Simulating Mediators of Delayed Hypersensitivity

THE aggregation of phagocytic cells at inflammatory sites is a characteristic feature of the defence of multicellular organisms against potentially injurious agents¹⁻⁴. From the point of view of comparative immunity, it is the one clear-cut similarity between vertebrates and invertebrates. Although multiple mechanisms may exist which control the accumulation of these cells, the obvious biological importance of this common defence system suggests the conservation of its principal elements in evolution. We have investigated the effects of macrophage-active factors from an invertebrate source on vertebrate (mammalian) inflammatory mechanisms.

Echinoderm phagocytes (coelomocytes) aggregate *in vivo* after an injection of inorganic particulate material, bacteria, or foreign cells⁵⁻⁷. Recently, Bang and Lemma have described the response of the sea star to a local injection of coelomocyte lysate into the coelomic cavity of the donor or other intact stars⁸. This response could be observed by direct microscopy of the living animal, and was characterized first by local, and later more peripheral clumping of coelomocytes within the respiratory papulae of the injected arm. We chose this whole cell lysate as the starting material for our investigation.

Sea stars (*Asterias forbesi*) were collected from the waters surrounding Woods Hole, Massachusetts, and "bled" by amputation of the tip of one or more arms; the coelomic fluid was drained into glass beakers. Following spontaneous agglutination and settling at 4° C, the coelomocytes were washed twice in seawater and a 20 per cent suspension (by volume) was lysed by brief ultrasonication. The product was centrifuged for 2 h at 60,000g and the clear supernatant concentrated by vacuum pressure dialysis to a final protein concentration of 3 to 5 mg/ml. The injection of as little as 20 μg of this supernatant in 0.1 ml. artificial seawater diluent into the arm of intact stars caused prompt, tight aggregation of coelomocytes circulating in the respiratory papulae of the injected arm. Aggregates of cells fixed to the walls of these structures and remained immobile for approximately 20 to 40 min, after which they slowly dispersed. This behaviour is essentially identical to that described previously⁸.

The activity of this material in mammalian systems was first investigated by intracutaneous injection of comparable amounts of whole coelomocyte lysate made isotonic by dialysis against 0.01 M phosphate-buffered saline (pH 7.4) into normal Hartley strain guinea-pigs. Begin-

Fig. 1. Sea-star coelomocyte euglobulin preparation eluted from 'G-75' column by 0.01 M sodium acetate buffer in 0.15 M NaCl (pH 5.0), giving two major protein peaks revealed by Folin analysis. The vertical bars through peak II represent the diameters of 24 h indurated skin lesions produced by intracutaneous injection of 0.1 ml. of individual fractions eluted under this peak.

ning at 6 to 8 h, an erythematous indurated lesion resulted which reached its maximum size between 24 and 48 h, after which it slowly resolved. The response was temporally, physically and histologically indistinguishable from that of cutaneous delayed tuberculin hypersensitivity. Similar reactions could be elicited in normal rabbits, mice, sheep, rats and day-old guinea-pigs following injection of this material. In no instance was there evidence of immediate skin reactivity.

Initial characterization of the whole coelomocyte lysate by 'Pevikon' block electrophoresis in 0.05 M veronal buffer (pH 8.2) localized the skin reactivity to cathodically migrating proteins. Immunoelectrophoresis using hyper-immune rabbit serum against whole coelomocyte lysate demonstrated two proteins in this peak: a strong arc in the γ^1 position and a fainter arc more cathodic in migration. These proteins were concentrated in the euglobulin fraction precipitated by dialysis of whole lysate against large volumes of 0.005 M phosphate buffer (pH 5.5).

Chromatography on 'Sephadex G-75' of the euglobulin preparation of coelomocyte lysate resulted in the elution profile of Fig. 1. Skin reactivity was confined to the second of the two major peaks (peak II) with an elution volume of 105 ml. Previous calibration of this column with protein markers of known molecular weight indicated that this elution volume lay between that of ovalbumin (94 ml.) and chymotrypsinogen (111 ml.), corresponding to a molecular weight of 32,000 by the method of Andrews⁹. Pooling all fractions of peak II followed by further concentration resulted in a single arc on immunoelectrophoresis identical to the γ^1 arc seen in whole lysate (Fig. 2). Skin reactivity per μ g protein of this purified fraction was greatly enhanced compared with whole lysate, so that 1 μ g was sufficient to induce an indurated lesion 12 mm in diameter which persisted for 48 h. Skin tests with 20 μ g of pooled peak I protein were negative. From these experiments we conclude that the delayed skin lesion in normal animals is dependent on the presence of γ^1 protein in the test material, and its severity directly proportional to the concentration of this component.

Delayed hypersensitivity in mammalian species has been shown to parallel the inhibition of macrophage migration during short-term tissue culture when cell populations containing sensitized lymphocytes are exposed to homologous antigen *in vitro*¹⁰. The interaction of lymphocyte and antigen results in the release of a non-specific migration inhibitory factor (MIF) which presumably acts on the macrophage cell population to inhibit normal migration^{11,12}. In similar *in vitro* experiments normal guinea-pig peritoneal macrophages were exposed to sea-star coelomocyte euglobulin preparations and fractions eluted by 'G-75' column chromatography. Significant inhibition of macrophage migration was seen in those cultures containing the γ^1 protein. Migration in

control cultures containing medium alone and in those containing 20 μ g/ml. 'G-75' peak I was similar. Medium containing 20 μ g/ml. euglobulin or 10 μ g/ml. 'G-75' peak II inhibited the average migration of macrophages to 51 and 53 per cent of control values respectively (Table 1). Inhibition of migration to the same degree could be demonstrated using macrophages separated from other cellular elements of the peritoneal exudate by plating on glass^{11,12}. Participation of the lymphocyte population in the exudate is not therefore required for the inhibition imposed by the presence of active sea-star material. Previous exposure and sensitization to cross-reacting antigens are therefore unlikely as an explanation of the action of this protein, for sensitized lymphocytes would be required for the generation of MIF. Peritoneal exudate cells exposed to medium containing 10 μ g/ml. 'G-75' peak II for 30 min and then washed and cultured in medium alone migrated to the same extent as controls, indicating that a primary toxic effect on the macrophages was unlikely. Exposure of the euglobulin preparation to 56° C for 30 min completely destroyed its ability to inhibit macrophage migration. From these experiments we conclude that inhibition of normal guinea-pig macrophage migration by sea-star coelomocyte lysate depends on the presence in the medium of the same protein as that responsible for the skin lesion in normal animals.

Intracellular proteins of the phagocytes of invertebrates may prove a fruitful source of evolutionary progenitors of those molecules concerned with immunological defence functions in the vertebrate species, as postulated by Burnet¹³. The position of the echinodermata immediately below the chordata in the phylogenetic scheme makes this large group of animals especially attractive as a starting point for such investigations. The possible relationship between the protein obtained from the sea-star coelomocyte and that produced by sensitized mammalian lymphocytes in the presence of homologous antigen is of particular interest. If the receptor sites on mammalian macrophages for the action of MIF are closely related or identical to that affected by the sea-star protein, these two effector molecules from different phylogenetic sources may be similar in structure as well as activity.

Selective Suppression of Cell Mediated Immunity by Equine Anti-rabbit Lymphocyte Serum

WE have investigated the effect of antilymphocyte serum (ALS) on the humoral antibody response, in rabbits, which readily produce large amounts of circulating antibody to well defined antigens. ALS was made by injecting a horse intramuscularly with a mixture of 2×10^8 thymus and lymph node cells from Himalayan rabbits, mixed with incomplete Freund's adjuvant. Seven days later the same

place by sutures. The dressings were removed on day 5, and the grafts were considered rejected when the skin became hard and scabbed over.

In the first experiment (Table 1A) the rabbits received a 12 day intermittent course of ALS or NES. ALS produced a striking prolongation of skin graft survival, with a mean for the group of 17.8 ± 0.8 s.e.m. days, compared with 9.5 ± 1.2 s.e.m. days for the controls. By contrast, ALS had no effect on the level of antibodies to bovine serum albumin (BSA) as measured by the indirect haemagglutination test, using the microtitre technique¹ after coupling the BSA to the sheep erythrocytes by the bis-diazotized benzidine method². All rabbits treated with ALS made a normal primary response, and after another immunization a normal secondary response. All treated animals also had substantial quantities of antibodies against equine γ -globulin (EGG).

These findings were checked by giving two groups of white NZ rabbits skin grafts, as before, on day 0, but no ALS. They rejected the grafts as expected. They also made a normal primary and secondary response to BSA. The 12 day intermittent course of ALS or NES was given, starting on day 68, and a second skin graft from the same donor strain was made on day 70. The NES group rejected the grafts with a mean of 8.25 ± 0.4 s.e.m. days, but with the group treated with ALS the survival of grafts extended on average to 16.5 ± 1.2 s.e.m. days (Table 1B). Immunization was carried out on days 70 and 91 with ovalbumin (OA), which has no groups to cross-react with BSA or equine albumin. As can be seen from Table 1B, the group treated with ALS made more antibody to OA and to EGG than the group treated with NES.

Clearly in the rabbit, ALS selectively suppressed cell mediated immunity but not the production of humoral antibody, either to well defined antigens such as BSA or OA, or to antibodies against horse proteins in ALS. Although ALS is known to be ineffective in suppressing antibodies against itself³⁻⁵ and to act "more effectively on the cellular than the humoral response" in mice⁶, our results are significant in showing that this dichotomy of effectiveness is complete in rabbits.

Table 1. EFFECT OF ALS ON SKIN ALLOGRAFT SURVIVAL TIMES AND ON HUMORAL ANTIBODY PRODUCTION

Detection of Actomyosin-type Protein at the Surface of Dissociated Embryonic Chick Cells

WE have previously shown¹ that antibodies prepared against smooth muscle actomyosin and capable of reacting with fibroblasts of connective tissue and with thrombocytes (platelets) markedly reduced the aggregative competence of embryonic chick muscle and liver cells. These antibodies were type specific and did not react with skeletal or cardiac striated muscle actomyosin nor with the (Na⁺,K⁺,Mg²⁺)-ATPase from human erythrocyte ghosts². The same antibodies blocked the activity of the Ca²⁺-dependent myosin ATPase of smooth muscle actomyosin³. Antibodies directed against striated muscle actomyosin and capable of blocking the activity of the Ca²⁺-dependent ATPase of this protein did not produce the aggregation-inhibitory effect. This led to the suggestion that the effect was the result of the antibodies against smooth muscle actomyosin reacting with an actomyosin of similar type at the surface of the muscle and liver cells⁴.

These findings are in keeping with the theory that a surface-localized actomyosin-like protein with rudimentary contractile properties is involved in cell adhesion⁵ and might be concerned with the movement of linkage sites⁶⁻⁷, on which adhesion may depend. But the results hitherto did not provide evidence indicating attachment of the "inhibitory" antibodies to analogous antigens at the cell surface: such evidence would validate the suggestion that the aggregation-inhibitory effect was accompanied by the reaction of the "inhibitory" antibodies with surface-localized antigens. We now report the results of experiments, using the fluorescent antibody technique, which reveal the presence of actomyosin-like protein with an antigenic similarity to smooth muscle actomyosin at the surfaces of muscle and liver cells from chick embryos.

The required tissue from 9 day old chick embryos was dissociated into separate cells with 0.25 per cent trypsin in Hanks balanced salts solution⁸. The cells were suspended in Eagle's minimal essential medium containing 10 per cent calf serum, and cultured in Leighton tubes at 37° C for 24 h. The γ -globulin fractions prepared from antisera against smooth muscle actomyosin of chicken gizzard (GAM) and chicken pectoralis muscle actomyosin (PAM), respectively, were conjugated with fluorescein isothiocyanate^{9,10}. The cells attached to the coverslip were washed with Dulbecco physiological saline before being treated with the conjugate¹¹. The preparations were washed thoroughly and mounted in 70 per cent glycerol-glycine buffer (pH 8.6)¹⁰.

The surface of the cells from both the embryonic muscle and liver tissue reacted—according to the distinctive green fluorescent staining—only with the anti-GAM γ -globulins. These, we have shown (unpublished results of R. B. K., B. M. J. and U. G.-S.), inhibit cell aggregation as effectively as antiserum against actomyosin from uterus smooth muscle (anti-UAM)⁴. The anti-GAM γ -globulins were irreversibly attached to surface antigenic sites. The conjugated γ -globulin fractions from both the pre-immunization rabbit serum (control) and the anti-PAM serum did not stain the cell surface.

Thus fluorescent anti-GAM γ -globulins can react with surface-localized actomyosin-like protein having antigenic properties similar to that of smooth muscle actomyosin. Such a reaction between GAM γ -globulins and the surface of the embryonic chick cells, leading to a reduction in the aggregative

competence of these cells, strengthens the view¹ that cell adhesion involves the participation of surface-localized actomyosin-like protein.

We thank Mrs Barbara Jones and Miss Barbara Morris for skilled technical assistance, the Science Research Council for grants and the Deutsche Forschungsgemeinschaft for aid in this investigation. U. G.-S. received a grant from EMBO for work in the Cellular Biology Unit of this department.

Structure of the Subunits in the Thick Luminal Membrane of Rat Urinary Bladder

A SUBSTRUCTURE of hexagonally arranged subunits has been reported in the luminal membrane of the superficial cells lining the rat urinary bladder^{1,2}. Preliminary examination of electron micrographs of negatively stained membranes in an optical diffractometer (unpublished observations of R. M. H., R. W. Horne and G. J. Hills) suggested that each subunit was a hexamer composed of six smaller particles. Vergara, Langley and Robertson³ described a similar hexagonal lattice in the mouse bladder luminal membrane. Their optical filtering technique revealed a lattice of hexamers skewed by 19° to the axis of the lattice. This communication describes how further detail has been resolved in the substructure of the membrane by a modification of the linear integration technique of Markham, Hitchborn, Hills and Frey⁴.

Fig. 1. A fragment of rat bladder luminal membrane, obtained by negatively staining fresh scrapings of transitional epithelium with 2 per cent potassium phosphotungstate, pH 7.2. The stain reveals a hexagonal lattice of subunits with a centre to centre spacing of 140 Å–150 Å. ($\times 200,000$.)

Scrapings of fresh, untreated rat bladder membranes were negatively stained with potassium phosphotungstate or ammonium molybdate and examined in either an Elmiskop 1 or AEI 801 electron microscope. Selected negatives were examined in an optical diffractometer. Of the sixty membrane sheets studied (Fig. 1), two were selected for high resolution and sharpness of diffraction spots. Linear integration was carried out in two different directions to obtain the average structure of up to 200 subunits in the lattice. Both the areas integrated showed subunits with twelve regions of high density (Figs. 2-5); the micrograph which showed diffraction spots up to the fourth order (Fig. 2) gave only poor contrast (Fig. 3) while the other which showed diffraction spots up to fifth order (Fig. 4) gave a clearer integrated picture (Fig. 5).

The information obtainable from a micrograph depends on the resolution of the original image. Thus illustration of twelve particles per subunit does not necessarily conflict with earlier reports in which only six were observed. The twelve particles can be seen only faintly if the image

Fig. 2. Optical diffraction pattern of an area of membrane stained as in Fig. 1.

Fig. 3. Area of membrane producing the diffraction pattern of Fig. 2, processed by linear integration in two directions inclined at 60° . ($\times 720,000$.)

Fig. 4. Optical diffraction pattern of a second area of membrane, stained as in Fig. 1.

Fig. 5. Integrated photograph of the area of membrane producing the diffraction pattern of Fig. 4. ($\times 720,000$.)

gives diffraction spots to less than the fifth order of resolution.

These results indicate that bladder membrane subunits are composed of twelve, rather than six, smaller particles, arranged in a stellate configuration. The subunits are thus dodecamers, not hexamers. As in the mouse bladder membrane³ the subunits are skewed by 19° to the main axis of the lattice.

We thank Dr R. W. Horne for advice and discussion, and Dr P. D. Cook for encouragement and the loan of equipment.

Non-solvent Water in Muscle

It is well established¹ that the structure of water in the vicinity of any surface is different from that of bulk water; also, nuclear magnetic resonance and dielectric relaxation studies have shown that, both *in vitro* and *in vivo*, the water adjacent to proteins and other macromolecules is oriented and its motional freedom is impeded²⁻⁶. Furthermore, water exerts a significant stabilizing effect on the structure of some macromolecules⁷⁻⁹. But there is still considerable debate¹⁰⁻¹⁶ concerning (1) the ability of the water of hydration of intracellular proteins to participate in osmotic changes occurring when cells are placed in hyper or hypotonic solution, and (2) the amount of osmotically inactive water in cells in normal physiological conditions. I wish to report a change in the space accessible to dimethyl sulphoxide in isolated guinea-pig intestinal smooth muscle induced by cooling the muscle from +37° C to -7° C in the absence of ice crystal formation. Dimethyl sulphoxide (DMSO) is a polar, water-miscible non-electrolyte which can form hydrogen bonds only by accepting hydrogen (by contrast, water is an acceptor and donor of hydrogen bonds). The kinetics of permeation of DMSO in smooth muscle have been studied previously¹⁷ and this non-electrolyte has been used with some success in preventing damage to smooth muscle exposed to sub-zero temperatures^{18,19}.

Strips of smooth muscle (taenia coli from albino guinea-pigs) were tied at their *in vivo* resting length to quartz frames and their blotted wet weights were measured at various intervals during 30 min of incubation in a continuously oxygenated (O₂/CO₂, 95/5 per cent) Krebs solution at +37° C. One group of muscles was then immersed at +37° C in a Krebs solution containing 20 per cent (w/v) DMSO (BDH, redistilled under vacuum), and a second group was incubated at +37° C in a similar solution containing 5 µCi/ml. of ³⁵S-DMSO (Radiochemical Centre, Amersham). After equilibration for 60 min, muscles were taken from their solutions, surface fluid was removed by a standard blotting technique¹⁷ and the muscles were weighed on a torsion balance. Non-radioactive muscles were then dried to constant weight at 105° C, and the radioactive muscles were placed in 5 ml. of Krebs solution at room temperature and the radioactivity was leached out overnight (there was no increase in the activity of the washout fluid after this period of leaching). Two other groups of muscles were treated in a similar way, but after incubation at +37° C the muscles were cooled to -7° C (that is approximately 0.5° C above the freezing point of the bathing medium) and left for a further hour at this temperature before the usual blotting, weighing and drying (or leaching) procedures were carried out. All solutions were continuously bubbled with the O₂/CO₂ mixture above and below 0° C, and the temperature was controlled to within ±0.5° C. The activity of ³⁵S-DMSO in the washout and loading solutions was assayed by liquid scintillation counting¹⁷ and the density of 20 per cent (w/v) DMSO-Krebs solution was measured at +37° C and at -7° C using a pycnometer with ethanol (Hopkin and Williams analar grade 99.5-100 per cent v/v) as the density standard.

The blotted wet weight of muscles, after 60 min in 20 per cent (w/v) DMSO-Krebs solutions at +37° C was not significantly different from the initial weight of the muscles in isotonic Krebs solution (although there was a transient loss in weight on immersion in the DMSO solution). The space accessible to DMSO represented 78.8 ± 0.7 (n=8) ml./100 g final weight of the muscle (mean ± s.e., n=number of observations), and the dry weight of the muscle together with the DMSO solution within the tissue accounted for its entire wet weight¹⁷. After the extra equilibration period at -7° C, however, the space accessible to DMSO decreased to 71.9 ± 1.2 (n=9) ml./100 g, although the wet weight of the muscles remained unchanged at 99.5 ± 2.2 (n=12) per cent of the initial

value. The density of 20 per cent (w/v) DMSO-Krebs solution increased from 1.0247 ± 0.0003 (n=3) g/ml. at +37° C to 1.0412 ± 0.0007 (n=3) g/ml. at -7° C, and so the space occupied by DMSO at -7° C was equivalent to 74.9 ± 1.2 (n=9) g/100 g, while the solids content remained unchanged at 18.5 ± 1.8 (n=6) g/100 g. Thus there was a significant change ($P < 0.01$ by the *t* test) in the space accessible to DMSO after cooling the muscle from +37° C to -7° C; and, while the water and DMSO spaces were identical at +37° C, the equivalent of 6.6 ± 2.2 g of water for each 100 g of muscle did not act as solvent for the DMSO at -7° C.

Although muscles do not contract in the presence of DMSO at concentrations greater than about 5 per cent (w/v)²⁰, in these experiments muscles suffered no irreversible changes by exposure to DMSO (20 per cent w/v) as judged by their contractile response to histamine when DMSO was removed at +37° C (ref. 19). Furthermore, even though it could be argued that the high concentrations of unlabelled DMSO might have disrupted water structure in the vicinity of proteins—thereby giving apparently equivalent solvent and total water spaces in the muscle at +37° C—preliminary experiments using trace amounts of ³⁵S-DMSO only in the Krebs solution at +37° C (with less than 10⁻⁴ M unlabelled carrier) indicated that the water and DMSO spaces were still identical. This identity between total and solvent water could arise in the unlikely situation that an amount of DMSO equal to that excluded by "bound" water on proteins was adsorbed on to the proteins; in fact, adsorption phenomena usually result in apparently negative amounts of non-solvent water¹¹.

These results support the finding²¹ that the value of Ponder's R (ref. 22) for smooth muscle cells of the guinea-pig taenia coli is unity at +37° C (assuming that collagen in the extracellular spaces provides a negligible contribution to the dry weight of the tissue). Thus at physiological temperatures and tonicities, the concepts of Ling²³ and Troshin²⁴, which involve binding of solutes on to intracellular proteins and low solubility of solutes in intracellular water, need not be used to describe the distribution of ions in smooth muscle²⁵.

The appearance of a non-solvent water fraction at -7° C is not surprising, and a similar tendency has been observed¹³ in human erythrocytes between 25° C and 0° C; however, it is not necessary to assume that this represents a specific conformational change equivalent to low temperature denaturation of proteins²⁶. Any orientation of water, by virtue of its dipole properties, in non-uniform field gradients associated with charged groups on proteins is opposed by the thermal energy of the water molecules, and cooling the system will merely tighten up the structure of the water lattice at the surface of the protein, thereby preventing the probe molecule from being accommodated into the lattice. In this respect measurement²⁷ of the amount of water that cannot be frozen out of solution at -20° C or lower is not a useful criterion¹¹ for non-solvent water in cells at physiological temperatures.

Proteins in muscle constitute almost the entire weight of the dry muscle, and it has been estimated²⁸ that the cell membranes make up only about 0.4 g/100 g wet weight; thus water unable to act as solvent for DMSO at -7° C represents about 0.36 ± 0.12 g/g muscle protein, and it may not be fortuitous that this figure is in line with other estimates of the probable hydration of some proteins²⁹.

Although this and other work^{11,13,14,21} indicates that virtually all cell water is osmotically active in physiological conditions, a temperature-dependent, osmotically inactive fraction of cell water should be allowed for when the osmotic behaviour of cells is considered in the extreme conditions of hypertonicity and temperature encountered during freezing³⁰⁻³². Finally, it should be remembered that any apparently non-solvent water in cells can be

explained in terms either of a lowering of the activity of water in the vicinity of macromolecules or an increase in the osmotic (or activity) coefficient of the macromolecules themselves during the dehydration of cells^{12,33}; on the other hand it could be argued that partial exclusion of solute from cell water provides a physical basis for the thermodynamic concepts.

Closely Spaced Nodes of Ranvier in the Teleost Brain

ALTHOUGH there have been several studies of internode length of myelinated fibres in peripheral nerve^{1,2} and in main fibre tracts of the central nervous system^{3,4}, there has been only one report of internode lengths within neuropil and nuclear regions of the vertebrate central nervous systems (CNS)⁵. Internode lengths in uninjured peripheral nerves of fishes are always greater than 200 μ m (ref. 1), and studies with rabbit spinal cord suggest that 200 μ m is also a minimum periodicity in main fibre tracts of the CNS⁴. Bodian's study⁵ of internode lengths in CNS included observations of myelinated fibres in the preoptic area, hypothalamus, hypoglossal root and pyramidal tract of the adult opossum. Of fifty-four fibres represented in his chart 1, six had internode lengths of approxi-

mately 100 μ m or less; none had internode distances of less than 50 μ m. During a study of the oculomotor nucleus of the spiny boxfish *Chilomycterus* with the electron microscope, I have made numerous observations of fine myelinated fibres with internodes less than 20 μ m long and occasionally approximately 5 μ m long. Tissue was fixed by perfusion with buffered solutions of osmium tetroxide or glutaraldehyde followed by osmium tetroxide, and prepared for microscopy as reported before⁶.

Fig. 1. Electron micrograph from the oculomotor nucleus of the spiny boxfish *Chilomycterus*. A myelinated fibre can be seen crossing the field from right to left. It forms a synaptic terminal (T) in contact with an oculomotor neurone (M). A node of Ranvier (N) is seen, and is approximately 16 μ m distance from the axon terminal. ($\times 3,240$.)

Fig. 2. Electron micrograph of a section of neuropil in *Chilomycterus* oculomotor nucleus. A short myelinated segment, about 6 μ m long, separates two nodes of Ranvier (N_1 , N_2). En passage synapses are established with two adjacent dendritic processes (d_1 , d_2). ($\times 8,400$.)

Nodes of Ranvier were observed frequently in thin sections of the oculomotor nucleus of *Chilomycterus*. Synapses were established at many nodes, as has been reported in other parts of the vertebrate nervous system⁷⁻¹⁰. Synaptic specializations included presynaptic vesicles, thickened membranes separated by a synaptic cleft approximately 20 nm wide, and, at a proportion of synapses, close appositions^{6,11}. The unmyelinated portion of axon at the node could be considerably longer than 1 μ m. Branching of axons was observed at nodes of Ranvier. Some myelinated fibres could be followed for distances of 25 μ m or more along their axes, within a single thin section. Nodes of Ranvier were observed frequently in these longitudinally sectioned fibres, and internodes shorter than 20 μ m were common. Fig. 1 illustrates a preterminal myelinated fibre which forms a synaptic contact with an oculomotor neurone (M). The distance from the node of Ranvier (N) to the axon terminal (T) is 16 μ m. Another example of a short internodal myelin segment is shown in Fig. 2; the distance between nodes of Ranvier is 6 μ m.

On theoretical grounds, Rushton¹² has argued that "it is only possible to argue from one nerve to another if certain proportions exist between their dimensions", and has noted that "nerve fibres do, in fact, exhibit the structural similarity demanded by the theory". Cragg and Thomas¹³ found that the relationship between internode length and axon and fibre diameters, one of the two geometrical conditions required for structural similarity, does not obtain for the lateral line nerve in trout, so that

Rushton's argument does not apply to this nerve. The present observations demonstrate that fine preterminal axons in the teleost brain may deviate considerably, in their pattern of myelination, from peripheral nerve tracts or main fibre tracts of the CNS, so that they do not exhibit "structural similarity" as compared with the latter groups of fibres. It follows that physiological arguments derived from these latter groups of fibres may not be applicable to fibres such as those I have described.

In electron microscopic examination of the oculomotor nuclei and sensorimotor cortex of the cat and rhesus monkey, I have failed to find internodes as short as those I have reported for teleosts. In the absence of precise data on internode distances, however, it is difficult to exclude the possibility of some fibres with internode distances smaller than 200 μm but greater than 20 μm , so that a complete internodal segment within the neuropil would rarely appear in a single thin section. Specification of internode distances, nodal areas and other anatomical parameters of myelinated fibres in neuropil and nuclear regions of the central nervous system will have to be accomplished before it is possible to predict the behaviour of these fibres.

This work was supported in part by grants from the US National Institutes of Health. I thank Dr G. D. Pappas for advice and support. I also thank Drs M. V. L. Bennett and D. P. Purpura for helpful suggestions.

Projection of the Lateral Eye of *Limulus* to the Brain

THE compound lateral eye of the horseshoe crab, *Limulus*, has been studied intensively for many years¹. It is relatively simple, consisting of a curved layer of interconnected ommatidia—about 1,000 or less in the adult. Each ommatidium contains two types of neurone: a group of reticular cells (ten to thirteen on average) and one, or occasionally two, eccentric cells². Although the axons of both types of cell leave the eye to form the optic nerve, evidence indicates that only the eccentric cell axons discharge nerve impulses in response to light¹. Thus the ommatidia communicate rapidly with the brain only through the impulse activity in the axons of their eccentric cells. (The function of the reticular cell axons in the adult remains obscure. They may have some neurosecretory activity, but apparently do not influence the brain directly by means of electrical signals.)

We describe here the spatial distribution of the eccentric cell axons as they enter the first optic ganglion of the brain. It is a step toward extending the analysis of visual mechanisms in *Limulus* from the eye into the cen-

tral nervous system. Some cells in the brain are known to respond to optic nerve activity with patterns of firing that resemble the activity of vertebrate retinal ganglion cells³; future work will deal with the properties of these and other central neurones.

In Fig. 1, photographs of a lateral eye (A), its optic nerve (B), and a first optic ganglion (C) are accompanied by a drawing that depicts the topographic relationships among these structures. The shape of the first optic ganglion—a thick neural sheet folded on the medial side and open laterally—has apparently not been previously described. With care it can be recognized in properly oriented sections of the brain, but it is often difficult to detect. The form is more easily observed by cutting through the chiasma between the first and the second optic ganglion⁴ and viewing the cut surface of the first ganglion.

Often, as shown here, the optic nerve fibres are grouped into distinct bundles distributed in roughly sequential

Fig. 1. Mapping of the lateral eye of *Limulus* into the optic nerve and the first optic ganglion. A, Lateral eye with optic nerve (dorsal view) entering the brain in B. This particular nerve is divided into five natural bundles of fibres. Four of the bundles are visible; the fifth lies underneath. C, Proximal view of an isolated first optic ganglion from a different brain. The ganglion is still connected to the optic nerve, but it has been detached from the brain by cutting through the chiasma that joins the first and second optic ganglia. The boundaries of the horizontal bands of ommatidia that contributed active nerve fibres to the five bundles were outlined by placing twenty-three spots of white paint on the cornea; rectangular black-on-white dashes were added to the photograph later for clarity. (See text for details.) The eye is mapped, band by band, into the ganglion in the manner schematically indicated by the line drawing. The curvilinear sequence of circular cross-sections in C is a simplification, for the shapes of the bundles can be irregular, and the positions may be somewhat staggered. The length of the eye in A is about 10.5 mm along the major (antero-posterior) axis. The scale for C is approximately the same as for B.

fashion along the fold of the first optic ganglion. Demoll⁵, who first observed these bundles, saw only three, but we find great variations from animal to animal. In some specimens the optic nerve has no visible divisions, while in others there may be as many as eight or more distinct bundles. What is likely to be important to *Limulus* is not the number of bundles, but the spatial mapping that they establish between the eye and the brain. For the experimenter, however, the bundles provide a "ready-made dissection" of the optic nerve that discloses some aspects of the spatial relationships with particular clarity.

First, one of the lateral eyes, its intact optic nerve, and the forebrain⁶ were excised and placed in a plastic chamber containing Ringer solution (based on measurements of the ionic composition of *Limulus* serum reported in ref. 7; further details in ref. 8). Electrical recordings were made from the optic nerve bundles by means of a suction electrode system. (The device consisted of a disposable syringe (chosen because the rubber plunger provides a good seal) connected through O-ring fittings to a tapered polyethylene tube. A fine silver wire made contact with the Ringer solution that filled the tapered electrode. The use of suction electrodes was described in ref. 9.) Each bundle was cut where it entered the brain and was drawn up into a suction electrode of appropriate size to fit over it. Nerve impulses from the eccentric cell axons in the bundle were amplified and led to a loud-speaker for auditory monitoring. The ommatidia that contributed active fibres to the bundle under study were then stimulated and identified by exploring the eye with a small spot of light.

Three experiments, all giving similar results, were carried out. The first two showed that the active fibres of the optic nerve bundles arose from horizontal bands of ommatidia, and that the bands were arranged in a definite sequence. In the last and most elaborate experiment, the extent of each band of ommatidia was marked on the cornea while observing the eye through a dissecting microscope. The boundary of the band was located by moving a small spot of light exciting no more than two to four ommatidia over the eye until a position was reached where no more responses were evoked in the bundle being studied. This location was marked by a spot of white paint on the cornea, and the procedure was repeated until the outer limits of the band were outlined on the eye. After carrying out this process for each of the bundles (five in this animal) a photograph of the eye was taken (Fig. 1A). We also took photographs showing the optic nerve bundles from this eye (Fig. 1B), and a first optic ganglion from another animal (Fig. 1C).

The relative positions of the optic nerve bundles as they enter the first optic ganglion and the positions of the ommatidia from which they arise are depicted in the line drawings of Fig. 1. All our experiments have shown this same overall pattern. The most dorsal band of ommatidia sends inputs to the most dorso-lateral portion of the first ganglion, the next band of ommatidia projects to the adjacent region, and so on, with the most ventral band of ommatidia sending its active fibres to the most ventro-lateral portion of the ganglion. The net result is that the eye is mapped more or less continuously into the first optic ganglion. A striking feature of this mapping is that incoming fibres from ommatidia separated by a given horizontal distance can be much closer together than fibres from ommatidia separated by the same vertical distance.

So far we have not studied in detail the manner in which the antero-posterior dimension of the eye is represented in the first optic ganglion. But an antero-posterior mapping that occurred within the thickness of the neural sheet, roughly orthogonal to the curve of the fold, would preserve the continuity of the projection.

A second set of experiments was carried out to specify the relationships between the adjacent bands of ommatidia and the adjacent nerve bundles more precisely. With

Fig. 2. Drawing of a lateral eye of *Limulus* to show the detailed structure of the horizontal bands of ommatidia that project to natural bundles in the optic nerve. Each ommatidium is represented by a circle in the diagram. In this animal the optic nerve was divided into eight natural bundles. The single or double slash in each circle identifies the particular bundle receiving an active fibre from that ommatidium. An empty circle indicates that no response was recorded from the ommatidium. Definitely established borders between the bands of ommatidia are marked by heavy lines. The ordering of the bands is the same as shown in Fig. 1, with band 1 projecting to the most dorso-lateral portion of the first optic ganglion and band 8 sending fibres to the most ventro-lateral region. The antero-posterior length of this eye was 12.5 mm.

slightly modified techniques (wick electrodes; nervous system exposed but remaining *in situ*) recordings were again made from the natural bundles as they entered the brain. But in this case, the ommatidia were illuminated one at a time by light from a single (76 diameter) fibre optics light guide^{10,11}. The cornea was marked at intervals and notes were made so that each ommatidium could be identified with the nerve bundle containing its eccentric cell axon.

All these experiments gave consistent results; the outcome of one experiment is summarized in Fig. 2. For this illustration the eye was photographed and a tracing was made of the ommatidial array. Each circle represents a single ommatidium, and the slashes within the circles identify the bundle of the optic nerve that received an active fibre from the ommatidium.

There is no overlap between the bands of ommatidia that project to different nerve bundles. Furthermore, some of the bands (for example, four and seven) extend the entire length of the eye without interruption, even though they are as narrow as one or two ommatidia at some points (compare Fig. 1). Within the limits imposed by the irregularity of ommatidial spacing, the boundaries between bands are either nearly straight lines or very gentle curves.

This strict segregation of the visual input into discrete horizontal bands may be associated with the mode of growth of the lateral eye *Limulus*. According to Waterman¹², the lateral eye is roughly circular in young animals, but later grows much more rapidly along the horizontal axis than along the vertical axis. He suggested that this elongation of the eye is accomplished by a proliferation of ommatidia in a growth zone at the posterior margin. Thus the horizontal patterning of the optic nerve projection could be achieved by the simple aggregation of fibres from neurones of a common parentage. If this affinity among growing nerve fibres promoted the establishment of the inhibitory connexions within the eye, then a basis would also be provided for the observed horizontal elongation of the inhibitory fields^{10,11}.

Earlier experiments had already shown that bundles of fibres dissected from the optic nerve near the eye frequently originate in horizontal bands of ommatidia (ref. 11 and unpublished results of B. Knight and F. A. Dodge). This, too, is consistent with the proposal that the horizontal organization is established at the eye, even though it is most easily demonstrated by studying the nerve bundles as they fan out and separate at the brain.

We still do not know whether the horizontal organization of the visual input has some special adaptive value for *Limulus*. It may be related to the immobility of the eyes, which are fixed on the carapace with respect to the ground and the horizon. If so, a similar pattern of pro-

jection might be expected in some of the other arthropods with compound eyes fixed on an immobile head, such as isopods.

Changes in Behaviour with Repeated Testing under the Influence of Drugs: Drug-experience Interactions

WHEN female rats are injected with a "mixture" of 15 mg/kg of amylobarbitone sodium and 0.75 mg/kg of amphetamine sulphate, and are then placed in a Y-shaped runway, there is a striking increase in their activity, greater than the increases produced by any dose of either drug alone¹. This mixture, although containing a greater proportion by weight of barbiturate, has similar effects to the combination used in the commercial preparation 'Drinamyl'¹. When the procedure is repeated on the same rats over many days there is a decline in the hyperactivity produced by the mixture, which stabilizes after the first few tests at a much lower level².

Several factors could account for this decline. First, the rats may become tolerant to the pharmacological effects of the drug with repeated administration. This seems unlikely, however, for we have not been able to detect any pharmacological tolerance in rats after as many as twenty-five daily injections of this dose of the mixture³. A second possibility is that the decline results merely from repeated exposure of the animals to the same environment, and is therefore a consequence of behavioural habituation⁴. Third, it has been suggested that the decline is due to some form of "behavioural tolerance"⁵. This is usually observed in situations where the effect of a drug is to produce some deficit in behaviour for which the organism can learn to compensate; with repeated testing under the influence of the drug the initial behavioural effect may disappear, although the pharmacological effect can be shown to be unchanged⁶. For behavioural tolerance to occur the organism must experience the drug and the test at the same time; behavioural tolerance can thus be

described as an interaction between exposure to a test and the presence of a drug.

In the experiment reported here we have attempted to assess the contribution of each of these factors to the changes in behaviour resulting from repeated testing with the mixture in the Y maze. To achieve this, the effects of three treatments had to be observed: (1) exposure to the drug without testing (pharmacological tolerance?); (2) exposure to the test without drugs (behavioural habituation?); (3) exposure to both drug and test simultaneously (drug-experience interaction, behavioural tolerance?). The effects of these three treatments had to be compared with the effects of the drug on "naïve" animals which have had experience of neither the drug nor the test. For "behavioural tolerance" to be demonstrated, the decline in activity with repeated testing under the drug should be greater than the decline due to both pharmacological tolerance and behavioural habituation.

Female hooded rats, bred by Animal Suppliers Ltd, were housed five per cage and allowed free access to food (Wyatt's GR/R/3) and water. They were 70–75 days old at the start of the experiment and weighed between 140 and 185 g. There were six groups of ten animals each. Before a final test in the Y maze with the mixture, four of the groups were pretreated as follows: groups 1 and 2 received twenty-four daily injections of either the mixture (group 1) or saline (group 2) after which they were returned to their home cages. Groups 3 and 4 were given twenty-four daily trials in the Y maze preceded by an injection of the mixture (group 3) or saline (group 4). Group 5 was given twenty-four daily saline injections and group 6 had twenty-four daily trials in the maze, preceded by saline injections. Both groups were therefore handled; they were given saline on the test day and thus served as controls. All injections were given subcutaneously 35 min before a trial in the maze. The mixture was given in the same dose as used previously^{2,3}, 15 mg/kg of amylobarbitone sodium and 0.75 mg/kg of amphetamine sulphate in the same solution. We allowed 1 day without any trials or injections between the end of the pre-treatment phase and the final test in the runway in order to minimize the possibility that any drugs previously injected were still present⁷. The testing procedure has been described before^{1,3}. A trial lasted 3 min during which the number of entries into an arm of the maze, rears, faecal boluses and urinations was counted. Our discussion is confined to entries which yielded the most consistent and reliable results¹. An entry was scored if all four feet of the rat entered an arm.

Fig. 1 shows that there was a decline in the activity of group 3, drugged and tested in the Y maze for twenty-five trials, but it was not very marked ($F=2.55$, d.f.=4,36, $P<0.10$). Indeed, on the test day these rats were slightly but not significantly more active ($t=1.45$, d.f.=18) than rats which had neither been in the maze nor had any previous injections of the mixture (group 2), whereas their activity would be expected to be below that of group 4 on the test day if behavioural tolerance had developed. Comparison of group 2 and group 1, pretreated with the mixture for 24 days, shows that the latter were no less active under the influence of the mixture on the test day than animals receiving the drug for the first time ($t=1.19$, d.f.=18); that is, no pharmacological tolerance was evident, which confirms our previous finding³.

Exposure to the Y maze without drugs, however, drastically reduced the drug response (groups 2 and 4: $t=3.78$, d.f.=18, $P<0.001$). Group 4 showed only a slight increase in activity when given the mixture on the test day (groups 4 and 6: $t=1.85$, d.f.=18, $P<0.05$). Their score was not different ($t=0.33$, d.f.=18) from that of undrugged animals introduced to the maze for the first time (group 5). Rats of group 5 were significantly more active than those of group 6, with previous experience of the Y maze without drugs ($t=1.97$, d.f.=18, $P<0.05$). This result is evidence that behavioural habituation⁴

Fig. 1. Y maze activity of different groups of rats. Each point is the mean of results for ten rats. ○, The mixture (15 mg/kg of amylorbarbitone sodium and 0.75 mg/kg of amphetamine sulphate). ●, Saline. Groups 3, 4 and 6 were injected as indicated and given twenty-five daily trials in the Y maze. The remaining groups received twenty-four daily pre-test injections of either the mixture (group 1) or saline (groups 2 and 5) and were tested only on day 26 after receiving the drugs indicated. There was 1 day without injections or trials between the end of the pre-test phase and the test day. ····, Daily temperatures during the course of the experiment (June 23–July 18, 1969).

had occurred in group 6. These findings are very similar to those obtained in studies of the effects of a single Y maze experience, with or without the mixture on reactions to the drug on a subsequent trial⁸.

In our results rats of group 2 were considerably less active on the test day after receiving the mixture than group 3 on the first day of the experiment, although both groups were receiving the mixture and performing the test for the first time; there was no difference between the corresponding saline groups (group 5 compared with groups 4 and 6). The interaction drug condition \times days is significant ($F = 11.59$, d.f. = 1, $P < 0.01$) and may be partially due to differences in temperature on respective days (13.67°C on day 1; 20.33°C on the test day, Fig. 1). Rats appeared to be less active and exhibit more ataxia on hot days (above 20°C). Thus differences in temperature may perhaps account for some of the changes in activity during the experiment.

In summary, we have found no evidence of pharmacological or behavioural tolerance. There was certainly an interaction between exposure to the Y maze and the presence of the drug (groups 1, 2, 3, 4: $F = 6.61$, d.f. = 1, 36, $P < 0.02$), but it was in a direction opposite to that required for behavioural tolerance; repeated testing with the mixture in the Y maze did not lead to any great reduction in activity, whereas exposure to the Y maze without the drug resulted in almost complete abolition of the drug response.

The problem posed is why this should be so. A possible explanation is that the mixture interferes with behavioural habituation⁴. Consistent with this interpretation is the finding that the decline in activity within a single Y maze trial is much less steep with the mixture than with saline¹. If behavioural habituation is retarded by the mixture, sustained activity in the presence of the mixture and a reduced effect of the mixture after behavioural habituation has developed would both be expected.

Rapid Eye Movements and Remembering

SOME theorists have ignored the content of dreams and concentrated specifically on chemical or physiological aspects¹. Oswald² has postulated that rapid eye movement (REM)³ sleep is a non-specific indication of many forms of synthesis within cerebral neurones, and that periods of massive learning would cause high percentages of REM sleep. Others have explained both dream content and REM state as playing a part in information processing. Some have used computer analogies, suggesting that reorganization takes place during the REM state, involving revision and updating of cognitive processes and memories⁴. It is known that remembering involves distortion and conventionalization⁵, so REM-induced reorganization should also show "effort after meaning".

Sleep has been shown to favour retention⁶ but it is not known how. If REM sleep is a positive process of consolidation and does not merely protect the trace from new input (as the "interference theory" of forgetting would predict) it might provide either a simple "setting" of the trace or an active reorganization and updating. If we measure the amount recalled by REM-deprived (RD) and non-REM-deprived (NRD) subjects and find that the latter retain more after sleep, it would support positive action theories against interference theories. If we examine the amount of organizational distortion and find more in the NRD subjects it would offer support to reprogramming as opposed to "setting" theories.

Our experiment involved ten pairs of male student volunteers, spending their second night in adjacent laboratory beds. At 2100 h the subjects listened to a tape recording of the material to be remembered. After lights-out one subject was randomly assigned to be REM-deprived, and whenever he showed signs of the REM state (according to a standard manual⁷) both were woken up, and kept awake for 5 min. The subjects got up at 0700 h and were immediately asked to recall in writing all the material learned the night before. This consisted of a list of thirty-two nouns, five sentences and a prose passage. The list was compiled from four categories (animals, vegetables, parts of the body and birds) arranged to give few consecutive category repetitions⁸. The five sentences were syntactically correct but meaningless (for example, "The academic liquid attended a deep bar")⁹. The list and the sentences were presented five times each, followed by two readings of a 162-word prose passage, specially written to contain several anomalies.

As intended, the principal effect of the regime was a very marked decrease in REM sleep in the RD subjects. They had, however, slightly less sleep altogether, and slightly more slow wave sleep (Table 1).

The amount of recall achieved by the two groups in the morning showed systematic differences: the RD group recalled less of all three sorts of material than the NRD group (Table 2). This effect was most marked in the recall of the prose passage, in both number of words used and accuracy scores—means of scores given by five "blind" independent judges, who agreed very highly significantly

Table 1. MEANS AND STANDARD DEVIATIONS OF THE TOTAL TIME (IN MINUTES) OF SLEEP STAGES ACHIEVED BY SUBJECTS IN THE TWO GROUPS

		Onset of sleep	Wake	I	II	III	IV	FEM Sleep	III +IV

* $P < 0.05$.† $P < 0.02$ (two-tailed).

with each other when asked to rate the material in a systematic way¹⁰.

Measures of restructuring of the word list¹¹ and sentences were both in the "reprogramming" direction, but not statistically significant. The RD group who remembered little of the prose passage, however, showed relatively more distortion than the controls.

Unfortunately, the difference in amount of sleep between the groups could have accounted for the differences in recall on an interference theory. The result of a conservative analysis of covariance, however, shows that the accuracy measure for the prose remains significant at the $P < 0.05$ level (two-tailed) when the variance attributable to amount of sleep has been taken into account.

It seems very likely, in the light of these results, that the REM state has an important part to play in the consolidation of memories, and that possible differences in restructuring remain worth pursuing.

Simultaneous Acoustic and Semantic Coding in Short-term Memory

It has been suggested^{1,2} that memory for verbal material comprises two components, one of which is labile and depends on the acoustic properties of the words while the other, which is more durable, is based on their meaning. The observed relationship between rate of forgetting and type of coding is explicable in at least the three following ways. (a) Material may pass from a short term store which uses an acoustic code into a long-term semantically coded store. (b) Material may be encoded on input either acoustically, in which case rapid forgetting occurs, or else semantically, in which case forgetting is relatively slow. (c) Material may be encoded both acoustically and semantically on input, in which case immediate recall will show the effects of both methods of encoding, but because the effects of acoustic coding are short lived, delayed recall will show only semantic effects.

The following experiment aims to decide between the three hypotheses. Subjects tried to remember sequences of three words which were either similar or dissimilar in sound and which either made up a meaningful phrase or were unrelated. The combination of two levels of acoustic similarity with two levels of semantic compatibility thus gave four basic conditions, similar and compatible, for example, "I might fly"; similar and incompatible, for example, "eye fight dry"; dissimilar and compatible, for example, "we could stop"; dissimilar and incompatible, for example, "king wake slit". Subjects attempted recall after either 2 or 20 s during which they were required to perform a distracting task. We assumed that a considerable short term component would be present after 2 s but would have dissipated after 20 s of distraction³. Subjects were successively presented with two sequences of three words on each test trial, the sequences being drawn from the same condition, and in the similar conditions they were acoustically similar to each other; for example, "Jude chewed food, lewd dude wooed". Each word was presented visually for 1 s.

The acoustic similarity effect is typically reflected in the difficulty of recalling the order in which items were presented rather than in recall of the items themselves, which may indeed be enhanced by acoustic similarity⁴. Item recall was not therefore required, the six relevant words on each trial being written in random order on a prompt card which was displayed during recall. To ensure that subjects could not respond correctly merely by rearranging the compatible sets to form meaningful triads, sets of three words were selected, which were comparatively meaningful in any of the six possible permutations of order, for example, "I might fly"; "might I fly"; "fly I might" and so on. Six subgroups of subjects were tested so that the six permutations of each triad were used once. For the intervening task, the experimenter read out random digits at a rate of one per second and subjects were required to add one to the digit and write down the answer. After two or twenty such digits they were given a verbal recall signal and shown the relevant prompt card, whereupon they attempted to write down the two word triads in the correct order. After 20 s the signal "ready" was given and the next trial began. The order of presentation of the four conditions and two delays was random. Six groups of five subjects were tested.

Performance was scored in terms of the number of words recalled in the appropriate serial position. The results (Table 1) were analysed using the Wilcoxon test with two-tailed significance levels. There was a reliable effect of semantic compatibility at both the 2 s ($t = 13$, $P < 0.01$) and the 20 s delay ($t = 8$, $P < 0.01$). The effect of acoustic similarity, however, occurs only at the short retention interval where it is shown by both compatible ($t = 45$, $N = 24$, $P < 0.01$) and incompatible triads ($t = 88$, $N = 27$, $P < 0.02$). At the longer delay, neither compatible nor incompatible triads show an acoustic similarity effect.

Table 1. MEAN PERCENTAGE OF WORDS RECALLED AS A FUNCTION OF ACOUSTIC SIMILARITY, SEMANTIC COMPATIBILITY AND RETENTION INTERVAL

Condition		Delay		Percent forgotten ($\frac{2\text{ s}-20\text{ s}}{2\text{ s}} \times 100$)
		2 s	20 s	
Compatible	Similar	61.0	68.9	-13.0
	Dissimilar	71.8	68.2	5.0
	Difference	10.8	-0.7	
Incompatible	Similar	42.8	40.9	4.4
	Dissimilar	52.2	46.0	11.7
	Difference	9.4	5.1	

Only the incompatible dissimilar triads show significant forgetting during the 20 s delay ($t = 90$, $N = 27$, $P < 0.05$), while triads which are both compatible and acoustically similar show a significant improvement in performance after the 20 s delay ($t = 60$, $N = 25$, $P < 0.01$).

These results are consistent with the hypothesis of simultaneous semantic and acoustic coding. Recall after 2 s uses both sources of information even though this is a sub-optimal strategy for one of the four conditions (acoustically similar compatible). Because acoustically coded information is rapidly forgotten, recall after 20 s depends chiefly on semantically coded information and the adverse effects of acoustic similarity are therefore absent.

We thank the Medical Research Council for financial support.

Axonal Transport of Neurotubule Protein

It has been known for some time that there is a constant somatofugal transport of materials down axons¹, but it has only recently been clearly demonstrated that more than one rate of transport may exist, and that transport cannot therefore be considered to be a single process²⁻⁴. As far as transport of protein is concerned, at least two mechanisms seem to be operating, at significantly different rates. First, there is a "fast" protein component, which, as our previous studies have shown, advances at a rate of about 50 mm per day in goldfish optic nerve⁵; its counterpart in mammalian nerve has been found to have a rate of up to about 500 mm per day^{6,7}. Second, there is a "slow" component whose rate of advance is about two orders of magnitude slower; the value in goldfish optic nerve was found to be about 0.4 mm/day (ref. 8), while in mammalian nerve, values of 1-10 mm per day have been observed². It is clear, moreover, that the fast and slow types of transport involve different cellular constituents, for the fast component consists almost entirely of insoluble—that is, particulate—protein, while the slow component contains about 40-50 per cent soluble protein^{5,9}.

We have now attempted to establish to what extent the neurotubule protein might be transported with either of the two components of protein transport. We took advantage of the fact that colchicine binds to neurotubule protein as it does to other types of microtubules, such as those in mitotic spindles, sperm tails and cilia¹⁰. We injected 2 μ Ci of [methoxy-³H]-colchicine (specific activity 5 Ci/mmmole) with a microlitre syringe into the posterior chamber of one eye of a series of goldfish of 5-7 cm in length. Both optic nerves and both optic tecta were then dissected out at appropriate intervals, the samples were dried and weighed, and tissue radioactivity was deter-

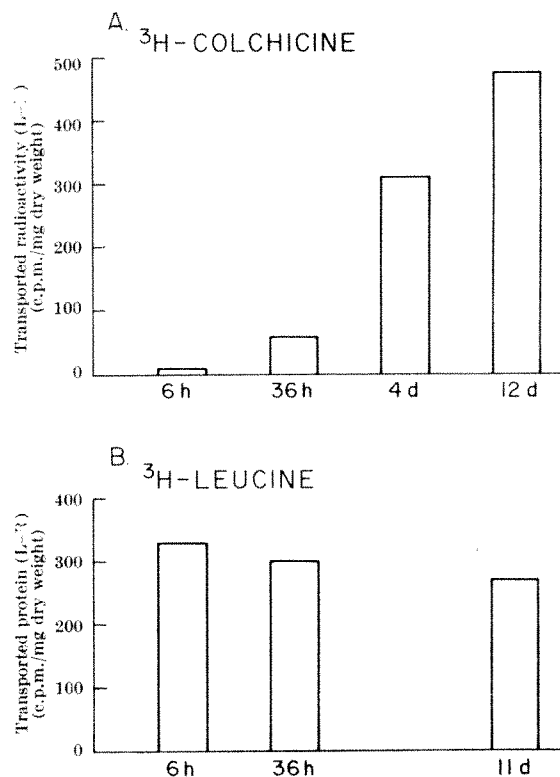

Fig. 1. A. Transported radioactivity in optic tectum after injection of 2 μ Ci ³H-colchicine into the right eye. B. Transported protein in tectum after similar injection of 4 μ Ci ³H-leucine. Each value is the difference between the left and right tecta in c.p.m. per mg dry weight, and represents the average obtained from five animals.

mined by an incineration technique¹¹. As has been shown⁵, a considerable proportion of the injected material is rapidly absorbed into the bloodstream, and gives rise to a certain level of "background" radioactivity on both sides of the brain. But only the optic nerve and tectum contralateral to the injected eye contain the labelled transported material, which is measured as the difference in "specific activity" (c.p.m. per mg dry weight) between the two nerves or two tecta. To determine the rate of protein transport, we injected 4 μ Ci of 4,5-³H-leucine (specific activity 5 Ci/mmmole) as above, and treated the tissue samples with either 10 per cent trichloroacetic acid or with Bouin's fixative to precipitate the proteins before incineration.

In Fig. 1, the time course of arrival of the transported labelled material after ³H-colchicine had been injected (1A) is compared with the time course of arrival of labelled protein after injection of ³H-leucine (1B). It is clear that the early appearance of labelled protein, which corresponds to the arrival of the fast component of protein transport, does not have any counterpart in the case of colchicine. At 24 h after the injection, for example, there is almost no transported colchicine.

Because the neurotubules may become disrupted when colchicine binds to them¹² it might be possible to ascribe the observed difference in the rates of arrival of labelled protein and colchicine to the fact that protein transport had been reduced in the presence of colchicine. Indeed, it has been reported that high levels of colchicine injected into a nerve may block fast protein transport entirely¹³⁻¹⁵. We found, however, that even at colchicine levels of 1 μ g per eye—about three times as high as those used in the experiment with labelled colchicine—neither fast nor slow protein transport was markedly affected (Table 1).

To determine whether the transport of labelled colchicine might be the result of a non-specific process such as diffusion or "interfacial creep"¹⁶, we tested for retrograde

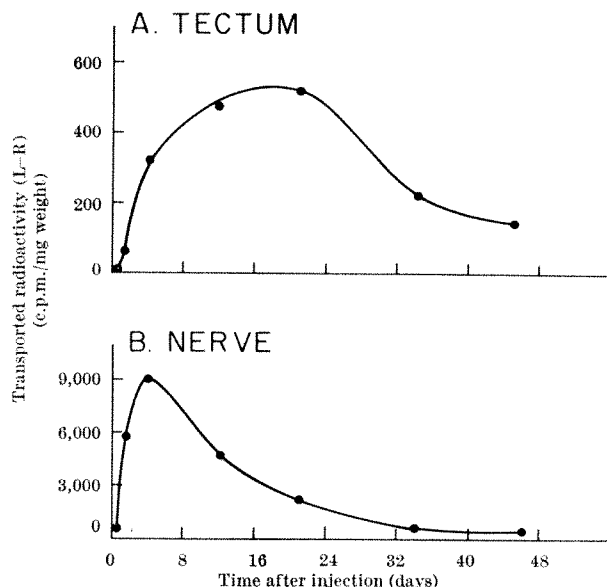

Fig. 2. Transported radioactivity in (A) optic tectum and (B) optic nerve after intraocular injection of ^3H -colchicine. Each point represents the average obtained from five animals.

transport, that is from tectum to retina. We injected 2 μCi of ^3H -colchicine intracranially, after crushing one optic nerve, so that although the injected material had access to the terminations of the optic nerves in both tecta, the transport of labelled material from tectum to retina could occur only on the side on which the nerve was intact, and would be expected to reveal itself as a difference in activity between the two retinas. Four days after the injection no such difference between the retinas was seen and it is unlikely, therefore, that a non-specific physico-chemical process could account for the transport of colchicine. Thus we presume that the colchicine was transported in association with the neurotubule protein.

To determine the rate of this transport, we compared the time courses of appearance of labelled colchicine in the nerve and in the tectum (Fig. 2). In the nerve, a peak in radioactivity was seen at about 4 days (2B), whereas in the tectum a much broader peak was seen at about 2-3 weeks (2A). The distance traversed from the middle of the nerve segment to the middle of the tectum was about 7 mm, so it can be estimated that the peak of the mass of radioactive material was advancing at a rate of 0.4-0.7 mm per day, which is clearly consistent with the previous estimate⁸ of 0.4 mm per day for the peak of the slow component of protein transport.

To confirm that the neurotubule protein was part of the slow component, we tried to isolate this protein from nerves which had previously been labelled by intraocular injection of leucine, at a time when the labelling of the slow component in the nerves was known to be high—at 6-16 days after the injection. Two different techniques were used, including ammonium sulphate precipitation followed by extraction on DEAE-Sephadex¹⁴, and precipitation with vinblastine¹⁸. Both gave disappointingly low yields with goldfish nerve, but when rat nerve

was used it was found that about 15 per cent of the soluble labelled protein in the nerve could be accounted for as neurotubule protein. (This is about as much labelled soluble neurotubule protein as can be extracted from the whole adult mouse brain 24 h after injection of labelled amino-acid¹⁹.) It is likely that the insoluble protein, which constitutes at least 50 per cent of the slow component^{5,9}, also contains an appreciable proportion of neurotubular material, and in the goldfish most of the neurotubule protein may be in the insoluble compartment.

Thus neurotubule protein is transported at the rate of the slow component of protein transport, but it does not constitute the whole of that component. This observation is particularly interesting in view of the suggestion²⁰ that the neurotubules might play a part in mediating fast transport. They evidently do not themselves move at the rate of the fast transport.

We have previously summarized evidence for the view that the material involved in the fast transport consists of vesicles and/or mitochondria⁵. It does not seem likely therefore that the formation of such vesicles could occur by the pinching-off of portions of the neurotubules, as some²¹ have suggested.

Table 1. EFFECT OF COLCHICINE ON ACCUMULATION OF RADIOACTIVE PROTEIN AFTER INTRAOCULAR ^3H -LEUCINE INJECTION

Colchicine injected (μg)	"Fast transport" (tectum 6 h after injection) (c.p.m./mg) (per cent)		"Slow transport" (optic nerve 12 days after injection) (c.p.m./mg) (per cent)	
—	208	100	1,597	100
10^{-4}	176	85	2,020	126
10^{-3}	172	83	1,646	103
1	207	100	1,307	82

One μl . of the colchicine solution in isotonic saline was injected into each eye 2 h after 4 μCi of ^3H -leucine was injected into the right eye, so that leucine incorporation was not interfered with. All values represent the difference between the labelled and unlabelled sides, in c.p.m./mg dry weight, and were obtained by pooling data from 3-5 animals in each case.

Psychological and Sociological Investigation of *XY* Prisoners

CYTOGENETIC surveys (Table 1) suggest that males with the sex chromosome constitution *XY* tend to be concentrated among tall detained delinquents, especially those with psychiatric disorder. We have carried out a survey of tall prisoners at a London prison, with a population which, although heterogeneous, is largely composed of recidivists from London and the Home Counties. For practical purposes we had to divide the surveyed popula-

tion, all of whom agreed to take part in the project, into the following groups. (1) Prisoners 6 feet tall and over, admitted to the prison in 1967 during limited periods governed by the availability of laboratory and other services. (2) Randomly selected prisoners 5 feet 11 inches tall and over, who were resident in March 1968. (3) Prisoners 5 feet 11 inches tall and over, admitted between September 15, 1968, and October 18, 1969.

Table 1. PREVIOUS CYTOGENETIC SURVEYS

‡ Personal communication from H. A. Lubs and F. H. Ruddle.

Leucocytes were cultured from 10 ml. of venous blood by Moorhead's²² method, air-dried and stained with Giemsa. Results are given in Table 2.

Table 2. INCIDENCE OF KARYOTYPE 47 XYF

Group	Specimens successfully cultured	Karyotype 47 XYF
1	34	2
2	31	1
3	290	6

Each subject with an XYF constitution was matched, from the same group, with a control of normal karyotype whose age was within 12 months and height within 3 inches of the subject, and who had been admitted as near as possible to the time when the subject had entered the prison. Ages ranged from 23 to 46 yr with a mean of 30. The mean height of subjects was 73.4 inches and of controls was 72.3 inches; six out of nine subjects were taller than their controls.

Sociological and criminological information about the prisoners was obtained from a standard questionnaire supplemented by police, prison, parole and probation records. As far as possible, data were expressed quantitatively and certain variables were used to construct rating scales. Subjects and controls were also examined physically and as many as possible were tested on the Wechsler adult intelligence scale; the Eysenck personality inventory (PEN); and the Foulds and Caine extrapunitive intrapunitive scale.

9	1	1

Four subjects but no controls had received treatment in mental hospitals.

Differences between pairs were evaluated by the Wilcoxon two-tailed signed ranks test. Differences at the 0.02 level of significance were found in respect of intelligence levels (Table 3) and the extent of previous psychiatric history (Table 4). The latter was estimated in numerical form by scoring each prisoner as follows:

for a history of psychiatric illness requiring institutional treatment, 3; for a history of psychiatric illness requiring only out-patient treatment, 2; for a history of untreated psychiatric disturbance, 1; and for no history of psychiatric disturbance, 0.

Differences at the 0.05 level of significance were found in respect of the number of previous convictions (Table 5) and a relative achievement scale (Table 6), the latter being a simply calibrated numerical expression of each prisoner's scholastic achievement and employment level relative to his father and brothers. Differences approaching this level of significance were found in respect of the number of previous accidents, the sum of theft and break-in offences and a sociability scale (Table 6) of eight questions bearing a substantial relationship to sociability, each item being scored as 0 in the direction of solitariness or 1 in the direction of sociability. This difference in sociability may be reflected in the extraversion scores of the PEN questionnaire (Table 7). Certain interesting data, although unproductive of significant differences, are given in Table 5.

Table 5. MISCELLANEOUS DATA ABOUT PRISONERS

	Mean values	
	XYF	Controls
No. of siblings	2.9	3.3

Control values given in parentheses.

Differences between family and school history of subjects and controls were appreciable but not statistically significant. One subject and three controls had a family history of psychiatric disorder; one or both parents of seven subjects and two controls had a history of alcoholism, and three subjects and four controls had a near relative who had been convicted of a criminal offence. Four subjects had attended schools for maladjusted or difficult children; none of the controls had been to such a school. Four subjects and one control had a record of truancy, and three subjects and one control had been expelled from school.

The comparison of employment between subjects and controls was mitigated by the large number and variety of jobs and a considerable degree of discrepancy between the various records. There remained a strong impression, however, that in general subjects were doing considerably less skilled work than the controls. The magnitude of the recorded discrepancies revealed no significant differences between subjects and controls.

Two subjects and one control could be regarded as heavy drinkers; three subjects and two controls had taken drugs but none could be described as addicts. There were no serious gamblers in either group. Six subjects and three controls had no established sexual partner. No subject or control professed homosexual tendencies but they were mentioned in the records of three subjects. Four subjects but no controls admitted having few or no girl friends before marriage.

Physical examination revealed tremor in two subjects, nystagmoid movements in three and stammer in two. Such features were not apparent in the controls apart from one case of tremor. Two subjects had pes cavus, and one slight facial hemiatrophy.

The conclusions are mitigated by the small number of subjects examined, the unassessed reliability of sociological data and the heterogeneity of controls. Nevertheless, we gained the impression that the XYY constitution in prisoners may be accompanied by the following tendencies (the first five of which occur with statistically significant frequency): (1) a past history of mental illness, often severe, and usually designated psychopathy; (2) lower than average intelligence; (3) higher frequency of convictions; (4) less achievement in comparison with father and brothers; (5) greater height in comparison with father and brothers; (6) a criminal history of offences against property; (7) asocial personality; (8) severe alcoholism of ascendants, usually father; (9) homosexuality, covert rather than overt. The degree of interdependence of these tendencies must remain speculative until a larger sample is available for analysis. The XYY constitution, however, has acquired some measure of definition and it might be profitable to explore its biochemical aspects in greater detail.

This work was supported by grants from the Mental Health Research Fund, the Home Office Research Unit and the South West Metropolitan Regional Hospital Board. The psychological results were elaborated through the help of Mr P. Rudgard and other psychologists of the Prison Service. J. Z. and T. A. were grant holders of the Mental Health Research Fund. This communication forms the basis of a paper presented in December 1969 at the Cropwood Round Table Conference at the Institute of Criminology, Cambridge University.

Abrin and Ricin: New Anti-tumour Substances

Abrin and ricin are highly toxic proteins isolated and crystallized from *Abrus precatorius*¹ and *Ricinus communis* respectively²⁻⁴. The LD₅₀s of abrin and ricin are 0.020-0.012 mg/kg body weight of mice respectively. Both have a molecular weight of 65,000, but a different chemical structure as judged by the analysis of N and C terminal amino-acid residues. For abrin these are leucine⁵, while the N-termini of ricin are alanine and isoleucine, and the C-termini are phenylalanine and serine^{2,6}. The biological activities of the two proteins are alike; both cause similar toxic symptoms and have no effect on mitochondrial respiration^{7,8}. The inhibitory effect of abrin and ricin on Ehrlich ascites tumour has been demonstrated by simultaneous injection of a sublethal dose with the tumour cells. Total inhibition of tumour growth in mice was demonstrated by measurements of body weight and total cell numbers in the peritoneal cavity. The therapeutic index of abrin was found to be 4. These inhibitory effects can be eliminated by heating the phytotoxin solution at 100°C for 30 min^{9,10}, which indicates that the anti-tumour activity of phytotoxins is due to protein.

We have used mice bearing Ehrlich ascites tumours, of various days' duration, to study the anti-tumour activity

Fig. 1. Effect of abrin on the change of body weight of mice given 2×10^7 Ehrlich ascites tumour cells and two single doses of abrin (0.2 μ g/mouse), each on days 8 and 11 as arrowed.

Fig. 2. Survival of mice treated with saline and abrin (injected on days 5, 7 and 9). A second injection was given on the third day after the first treatment. Each bar represents one animal.

Fig. 3. Effect of ricin on the changes in body weight of mice given 2×10^7 Ehrlich ascites tumour cells and two single doses of ricin ($0.2 \mu\text{g}/\text{mouse}$), each on days 3 and 4 as arrowed.

of abrin and ricin. The two toxins were dissolved in isotonic saline for injection. Although, when tumours develop, the weight of the mice increases by several grams, we used 20 g as the basis for our calculation of the dose in $\mu\text{g}/\text{kg}$ body weight.

In all experiments, NMRI male mice, average weight 20 g, were inoculated intraperitoneally on day 0 with 2×10^7 Ehrlich ascites tumour cells with 98 per cent viability demonstrated by the eosin Y exclusion method¹¹. A solution of abrin or ricin was injected intraperitoneally into the mice on days 1, 3, 5, 7, 8, 9 and 11. As a control, isotonic saline was injected after inoculation with tumour cells. Results were evaluated on the basis of a comparison of the average change in body weight of experimental and control mice.

When treatment of tumour bearing mice with a single sublethal dose ($10 \mu\text{g}/\text{kg}$ body weight) was initiated on days 1 and 3, the growth of Ehrlich ascites tumour was completely suppressed. Mice treated with abrin lost weight on the first day after treatment and then gradually gained weight to the level of mice not inoculated with tumour cells. Two doses of $10 \mu\text{g}/\text{kg}$ body weight were required to suppress the growth of tumour completely if the treatment was initiated on days 5 and 7. The second

dose was injected 3 days after the first. The results are summarized in Figs. 1 and 2. Once the tumour was cured, the mice survived during 50 days of observation and no tumour cells were detected. When toxin was injected on days 9 and 11 no complete cure of tumour was observed.

Ricin had a similar inhibitory effect on Ehrlich ascites tumour. For complete inhibition of tumour growth, a single sublethal dose of $7.5 \mu\text{g}/\text{kg}$ body weight was required on days 1 and 3 (Fig. 3). If the treatment was initiated on days 5 and 7 tumour growth was not inhibited. Fifty per cent of mice treated on day 5 did not develop tumours, while the life span of the rest of these mice and all those treated on day 7 was prolonged (Fig. 4).

Fig. 4. Survival of mice treated with saline and ricin (injected on days 3, 5 and 7). A second injection was given on day 1 after the first treatment. Each bar represents one animal.

Clearly abrin and ricin not only inhibit the growth of tumour at an early stage but can suppress the tumour completely after it has been developing for several days. Although the medical significance of this finding is not yet clear, our findings add to the biological properties of this class of phytotoxins.

Selective Inhibition of a Nuclear RNA Polymerase in Cells infected with Frog Virus

Frog virus (FV-3) is one of a group of polyhedral DNA-containing viruses, isolated from normal, tumour and diseased tissues of a variety of amphibia, which replicate within the cytoplasm of infected cells¹. FV-3 multiplies at 12° to 31° C, with a distinctive cytopathic effect, in cell cultures from both poikilothermic and homothermic (including human) vertebrates^{1,2}. The properties of the virion and the characteristics of virus replication have been reviewed by Granoff¹. The earliest demonstrable event in cells infected by FV-3 is a marked depression of cellular RNA synthesis, within 1 h of infection^{1,3}.

We have studied the influence of infection with FV-3 on the nuclear RNA polymerase (nucleoside triphosphate: RNA nucleotidyltransferase, EC 2.7.7.6) activities of baby hamster kidney (BHK 21/C13) (ref. 4) cells, to investigate if the inhibition of the cellular RNA synthesis could be accounted for by a depressed enzymatic activity. BHK cell cultures were grown in stationary Roux-type bottles, each containing 50 ml. of Eagle's basal medium

supplemented with 10 per cent calf serum. When cell monolayers were confluent, the growth medium was discarded and the cultures were infected with 12 ml. of serum-free Eagle's basal medium containing FV-3 in an amount calculated to give a multiplicity of infection of 2 p.f.u. per cell. After 1 h the inoculum was removed and the cell cultures were washed and re-fed with 50 ml. of serum-free maintenance medium. Unless otherwise stated, cell cultures were incubated at 26° C immediately after the infection.

For RNA polymerase assays, at various times (Fig. 1) —reckoned from the beginning of the infection without considering any dead time for virus adsorption—the medium was removed, the monolayer was washed twice with 0.85 per cent NaCl, cells were scraped off the bottles with a rubber policeman and were washed twice with the same solution. After 10 min swelling in 0.01 M Tris buffer (pH 8.0), the cells (approximately 7×10^7 /ml.) were disrupted with a Dounce homogenizer and "nuclear" and "cytoplasmic" fractions were obtained by low speed centrifugation (800g/10 min) at 5° C. Nuclei were washed and resuspended in Tris buffer. The RNA polymerase activity of the nuclear fractions was assayed in a low ionic strength system⁵ containing Mg^{2+} ("5 mM Mg^{2+} " system) and in a high ionic strength^{5,6} system containing Mn^{2+} and ammonium sulphate (" $Mn^{2+}/(NH_4)_2SO_4$ " system).

The rate of RNA synthesis was studied by pulse-labelling cell monolayers with ³H-uridine at various intervals after infection. The medium was removed and the culture bottles were supplied with 12 ml. of serum-free Eagle's basal medium containing 10 μ Ci/ml. of ³H-uridine (specific activity 1.8 Ci/mmol) in the presence of a 20-fold excess of unlabelled thymidine. After 10 min at 26° C, incorporation was stopped by washing the cultures with cold 0.85 per cent NaCl. The cell monolayers were then immediately processed as described to obtain separate nuclear and cytoplasmic fractions. DNA was determined by the method of Burton⁷, and protein by the method of Lowry *et al.*⁸. Uninfected control cell cultures, maintained in the same conditions, were simultaneously processed and tested in each series of experiments.

The results (Fig. 1) demonstrate that the marked depression of RNA synthesis in the nuclei of FV-3 infected cells—which is evident very early in the virus growth cycle—is paralleled by a selective inhibition of RNA polymerase activity detectable in the $Mn^{2+}/(NH_4)_2SO_4$ system; the polymerase activity demonstrable in the 5 mM Mg^{2+} system (not shown in Fig. 1) was practically unaffected. The same results were obtained in reactions at 26° C.

In the cytoplasmic fractions of FV-3 infected BHK cells, studied 1, 3, 8 and 24 h after infection, the RNA polymerase activity was always very low and of the same level as in uninfected control cell cultures. This was evident with the 5 mM Mg^{2+} and the $Mn^{2+}/(NH_4)_2SO_4$ systems, and with the assay system described by Pitkanen *et al.*⁹, both in the presence and absence of detergent (1 per cent 'Triton X'), in the presence or absence of calf thymus DNA primer, and in reactions carried out at either 26° C or at 37° C.

Because the inhibition of host cell macromolecular synthesis by FV-3 occurs at temperatures incompatible with virus replication, or in the presence of protein inhibitors^{1,3}, we have studied the behaviour of RNA polymerase activated at high ionic strength in nuclei of FV-3 infected BHK cells, at either 37° C or 26° C in the presence of 50 μ g/ml. of cycloheximide. Even in these conditions, the nuclei of cells infected by FV-3 have depressed RNA polymerase activity (Table 1), so that, as for the inhibition of host cell macromolecular synthesis, complete virus replication or *de novo* protein synthesis subsequent to infection is not essential for the inhibition of the nuclear polymerase. At the same time, the results suggest that the decreased enzymatic activity cannot be

Fig. 1. Top: virus yield in FV-3 infected BHK cell cultures, infected as described. At the times indicated on the abscissa, the fluid and the cells were collected separately. Cells were resuspended in serum-free maintenance medium (in a volume identical to that of the medium fluid) and frozen and thawed three times. The virus present in the medium fluid (\circ --- \circ) and that associated with cells (\bullet — \bullet) were titrated by plaque assay in BHK cells. Bottom: behaviour of high ionic strength activated RNA polymerase and rate of RNA synthesis in the nuclei of FV-3 infected BHK cells. Nuclear fractions were prepared as described. The $Mn^{2+}/(NH_4)_2SO_4$ system (Δ — Δ) contained, in a final volume of 0.5 ml., 50 μ moles of Tris-HCl buffer (pH 7.5), 2 μ moles of $MnCl_2$, 0.035 ml. of ammonium sulphate saturated at room temperature and brought to pH 7.5 with diluted ammonia solution (final concentration in the assay mixture 0.28 M), 0.9 μ mole each of GTP, CTP and UTP, 0.06 μ mole ATP containing 0.3 μ Ci of [³²P]ATP, and 0.1 ml. of nuclear suspension containing about 70 μ g DNA. For both systems, incubation was at 37° C for 10 min. The reaction was stopped by adding 5 ml. of 0.5 N HClO₄. The mixtures were filtered through fibre glass filters (Whatman 'GF/C') which were washed three times with HClO₄, and the radioactivity retained on the filters was measured in a liquid scintillation counter. For the determination of RNA synthesis (Δ --- Δ), "nuclear" fractions were treated with 5 volumes of HClO₄, and the precipitable radioactivity was collected and measured as described.

* After infection or after change of the growth medium with serum-free maintenance medium.

† In the presence of 50 µg/ml. of cycloheximide, protein synthesis in BHK cell cultures maintained at 26° C was inhibited by 92 per cent after 30 min, and by 95 per cent after 1 h, as judged by a further 30 min pulse with 0.5 µCi/ml. of ¹⁴C-protein hydrolysate (*Chlorella*, specific activity 52 mCi/milligram C).

‡ Experimental conditions as in Fig. 1.

ascribed solely to a reduced rate of synthesis of the enzyme, for nuclei from uninfected cells treated with a protein synthesis inhibitor for 36 h show only a moderate decrease in RNA polymerase activity.

The coincidence between the impairment of RNA synthesis and the diminution of the high ionic strength activated RNA polymerase activity strongly suggests that the inhibition of this enzyme is the mechanism underlying the impairment of RNA synthesis in FV-3 infected cells. The $Mn^{2+}/(NH_4)_2SO_4$ -activated RNA polymerase is also selectively inhibited by two toxic substances, α -amanitin¹⁰ and lasiocarpine^{11,12}. Inhibition of this polymerase activity in FV-3 infected cells is accompanied by depression of RNA synthesis, as in animals intoxicated with α -amanitin or lasiocarpine, and this further suggests that the high ionic strength activated RNA polymerase (which may be an enzyme different from that active at low ionic strength)¹³ may be functioning *in vivo*^{10,12,14}.

This seems to be the first example of the selective inhibition of a cellular RNA polymerase activity caused by viral infection. It is unlikely to be an unspecific consequence of viral infection, for in cells infected by vaccinia virus inhibition of RNA synthesis¹⁵ is not accompanied by significant changes in the nuclear RNA polymerase activities¹⁶.

Fluoroscopic Radiation and Risk of Primary Lung Cancer following Pneumothorax Therapy of Tuberculosis

STEINITZ has reported a remarkable epidemiological study in Israel which indicated that persons with a tuberculosis history, active or arrested, showed a five to ten-fold increase in the risk of subsequent development of primary lung cancer¹. Steinitz was, of course, acutely aware of the excessive risk of lung cancer in cigarette smokers and gave careful attention to this variable. Recently, she has also indicated that there is no reason to believe that persons with a past history of tuberculosis smoked cigarettes more than did those in the general population sample (personal communication). It therefore seems that by some mechanism other than cigarette smoking a record of extensive therapy of tuberculosis implies a high risk of primary lung cancer. The magnitude of excess risk of lung cancer in tuberculous persons is comparable with that for cigarette smoking in non-tuberculous persons. Is tuberculosis *per se* responsible for the observed excessive risk of future primary lung cancer? We think not. We propose that frequent fluoroscopies of the chest, associated with the past extensive use of pneumothorax collapse therapy, is the aetiological factor responsible.

Mackenzie, studying the records of a tuberculosis sanatorium in Nova Scotia, demonstrated a crude twenty-four-fold higher incidence of breast cancer in 271 patients treated with pneumothorax, compared with 510 women who did not receive such collapse therapy, and suggested that radiation may be the cause². Pneumothorax refills had usually been accompanied by a pre- and post-refill fluoroscopic examination. In Mackenzie's series, the average number of fluoroscopies was ~150 per patient treated with pneumothorax. Farber (personal communication) has confirmed that such a frequency of fluoroscopies agrees with his observations for the pre-1950 period in the western USA. From Mackenzie's data, an air dose of ~900 rads, for radiation penetrating 1 mm Al filtration, is indicated to the chest region. This corresponds to 150 fluoroscopies with the typical exposures which were then used. The dose to lung tissue must have been 900 rads or less, depending on the hardness of X-rays used. If those patients not receiving pneumothorax treatment are assumed to have no radiation dose, and if 900 rads are credited for patients averaging 150 fluoroscopies associated with pneumothorax treatment, the overall average lung dose for the Nova Scotia tuberculosis patients is

$$\frac{(900)(271) + (0)(510)}{781}, \text{ or } \sim 310 \text{ rads. Attenuation of radiation}$$

in the lungs would tend to lower this average dose, but the utilization of some fluoroscopies in the non-pneumothorax cases would tend to raise it. The 310 rad average dose is therefore not unreasonable.

Our best estimate, based on Court-Brown and Doll's³ X-ray treated spondylitis and Wanebo's⁴ atomic bomb survivors, is that a dose of ~50 rads produces a number of lung cancers equal to the spontaneous incidence (our unpublished results). Thus 50 rads would constitute a doubling dose for primary lung cancer, and the British and Japanese data, for widely different epidemiological samples, are closely consistent with each other. Thus in a tuberculosis hospital such as that reported by Mackenzie, the average patient would have received 310/50, or 6.2 doubling doses to the lungs. If the spontaneous incidence is added in, the overall lung cancer incidence would be 6.2+1.0, or 7.2 times the expected spontaneous incidence. Such variables as age, sex and cigarette smoking history must, of course, be comparable for the irradiated group and the base population sample.

The Steinitz series of primary lung cancers are for diagnoses made between 1960 and 1963. Because the

patients had had extensive, and in many cases repeated, courses of therapy for tuberculosis, it follows that many of her cases had been treated in the same time period (1940s and early 1950s) as Mackenzie's subjects. It is quite reasonable to believe that practices in tuberculosis therapy would have been similar for the Nova Scotia and Israeli tuberculosis patients. Furthermore, Steinitz indicated that cigarette smoking was not excessive in the tuberculous subjects. The observed five to ten-fold higher risk of primary lung cancer in Israeli tuberculosis cases is therefore consistent with the ~ seven-fold higher expected risk for a fluoroscopic radiation aetiology.

We strongly urge that our hypothesis is accepted only as a guide to valuable studies which can readily be made, and that it should not be considered, at this time, as a plea for reducing essential radiography or fluoroscopy in the management of a serious disease such as pulmonary tuberculosis. Medical practice has already shown concern over unnecessary radiation, and massive dosage reductions have been achieved in fluoroscopic examination.

We present this hypothesis because we believe that worldwide radiation standards are needed with respect to atomic energy development. Neither the Court-Brown and Doll spondylitis series nor the Hiroshima-Nagasaki series is large, and new cases of lung cancer will be added slowly. But records of lung cancer cases can be substantially increased through a worldwide epidemiological study of hospital and follow-up records. Internationally, a very large number of records for tuberculosis patients treated between 1930 and 1950 must be available. Because the latency period for cancer development in such cases would have expired by 1950-70, the relevant lung cancer cases have, in the main, already occurred. A record search plus follow-up should therefore enable fluoroscopic radiation to be evaluated as a possible aetiology of lung cancer in tuberculosis patients. Indeed, in many hospitals the records will be sufficiently accurate to determine the number of fluoroscopies per patient treated, as well as radiation dose per fluoroscopy, and this may even provide a dose-response curve for possible radiation-induction of lung cancer.

Such studies would be far superior, for evaluating this hypothesis, than our comparison of radiation dose in Nova Scotia with lung cancer incidence in Israel. The proposed studies would have internal controls in two important ways. First, within a particular study, the lung cancer incidence rate as a function of the number of fluoroscopies can be determined for non-smokers, and a similar comparison can be made for cigarette smokers. Second, the studies in a particular region in a single country would provide controls, similar to the irradiated persons, in all variables other than fluoroscopic radiation. Finally, while pharmacological agents should be considered, this factor would have been of little consequence for therapy before 1950. Indeed, a preliminary follow-up study by Hammond and co-workers provided no evidence for excessive cancer in tuberculosis patients treated with isoniazid, one of the chemicals reported to produce neoplasia in mice⁵. It is also of interest that Hammond reported no excessive cigarette smoking in 311 tuberculous subjects compared with non-tuberculous persons.

Synthetic Sweetener Consumption and Bladder Cancer Trends in the United States

RECENT experimental evidence has demonstrated that high doses of synthetic sweeteners cause bladder cancer in rodents. In rats, the oral administration of a cyclamate-saccharine mixture alone or combined with cyclohexylamine, a metabolite of cyclamate, induced a high frequency of bladder carcinoma¹. These tumours also developed in mice after bladder implantation of cholesterol-cyclamate or cholesterol-saccharine pellets^{1,2}. These studies prompted the Department of Health, Education and Welfare to restrict the general use of cyclamates and to undertake further laboratory studies on the toxicity of synthetic sweeteners. As a first step in evaluating whether synthetic sweeteners are carcinogenic in man, we have examined the consumption patterns of these agents and the trends for bladder cancer in the United States.

A dramatic increase in the consumption of artificial sweeteners began in the US in 1962, chiefly in the form of a 10:1 cyclamate-saccharine mixture (Fig. 1). The consumption of cyclamates rose from 2.7 million pounds in 1962 to 19.7 in 1969. Although the exposure to cyclohexylamine is unknown, it is present in some cyclamate-sweetened food as a result of processing, and in some persons cyclamate is metabolized to cyclohexylamine³.

Fig. 1. Cyclamate consumption in the US, by calendar year, 1950-1969 (unpublished data, US Department of Agriculture).

A wide variety of foods and drugs have contained synthetic sweeteners; about 70 per cent of all cyclamate-saccharine mixtures were consumed as soft drinks. While per capita consumption of these beverages was fairly uniform throughout all age groups, the greatest exposure occurred in persons between 16 and 19 years of age. In that age group, average daily cyclamate consumption from soft drinks was 1 mg/kg of body weight, and maximum intake about 50 mg/kg².

Death rates for bladder cancer were calculated for the US in 1950-1967, from mortality data on computer tapes representing death certificates kept at the National Center for Vital Statistics and from population data derived from published census statistics. Although there are differences in mortality by race and by sex, no clear-cut break in either age specific or age adjusted rates has occurred since the mass introduction of synthetic sweeteners in 1962 (Fig. 2). Because a person with bladder cancer may be cured or may survive for a long time, mortality is less sensitive than incidence in detecting a change in frequency. Study of age specific and age adjusted incidence rates for bladder cancer in Connecticut^{3,4}, supplemented by unpublished tabulations for 1965-1967, shows that recent trends are consistent with

Fig. 2. Bladder cancer death rates in the US, age adjusted, by race, sex, and calendar year, 1950-1967.

Fig. 3. Bladder cancer incidence rates in Connecticut, age adjusted, by sex and calendar year, 1950-1967. (Data for 1966 and 1967 are estimates corrected for delayed reporting.)

the slow, long-term rate of increase (Fig. 3). Incidence figures from New York state⁵, supplemented by unpublished data for 1961-1967, confirm this trend. Many epidemiological features of bladder cancer, such as the increasing incidence, male predominance and geographic variation, may be attributed to patterns of cigarette smoking, which increases the risk of this neoplasm about three-fold^{6,7}.

Although the mass introduction of synthetic sweeteners into the general diet has not influenced bladder cancer rates in the United States up to 1967, an oncogenic effect may have gone undetected if the dose were too low or if the observation period were too short. The dose per body weight which produced tumours in experimental animals was fifty times higher than the maximum amount ingested by man^{1,2}. Furthermore, only six years of observation have passed since the sharp increase in consumption of synthetic sweeteners, while the latent period averages twenty years for tumours induced by occupational exposure to aniline dyes, betanaphthylamine and other chemicals⁸.

The carcinogenic potential of cyclamate or cyclohexylamine is suggested not only by the induction of bladder tumours in rodents, but also by chromosome breaks *in vivo* in the spermatogonia and bone-marrow cells of rats⁹ and by chromosome breaks *in vitro* in human cells⁹. While detailed studies of bladder cancer trends in the general population should be continued over the next two or three decades, the long-term effects of cyclamates and other sweeteners may be detected more readily by monitoring special groups of heavily exposed persons.

We thank Mr John T. Flannery, Connecticut State Department of Health, and Dr Peter Greenwald, State of New York Department of Health, for incidence data,

and Mr Fred Gray, Economic Research Service, US Department of Agriculture, for estimates of US cyclamate consumption.

Control of Potato Gangrene and Skin Spot Diseases by Fumigation of Tubers with Sec-butylamine

FUNGAL diseases of potato tubers can cause considerable losses in the United Kingdom every year. At present in Scotland the most serious is gangrene, a rot of tuber flesh caused by *Phoma exigua* var. *foveata*. Skin spot, caused by *Oospora pustulans*, is also important, but in this case the organism does not rot tuber flesh: small pustules appear on the surface and, more importantly, eyes may be killed and sprouting affected.

These diseases have proved difficult to control chemically, and until very recently this has only been achieved by disinfecting tubers in solutions of organo-mercury compounds¹. Mercury treatment has been adopted commercially, but it suffers from several practical difficulties, and although used for many years has made only limited impact on the seed trade. Experimental use of the systemic benzimidazole fungicides is giving promising results, but these still have to be applied to tubers as dusts or in dipping solutions².

Gaseous treatment of tubers has not often been investigated, although formaldehyde gas has been tried unsuccessfully. Nevertheless, fumigation has attractive possibilities especially because gases could be introduced into bulks of stored tubers fairly easily. We tested several gases against pure cultures of gangrene and skin spot fungi but substances that seemed promising fungicides proved phytotoxic to tubers. Although sec-butylamine (2-aminobutane) had only a limited effect on growth of pure cultures, we decided to see whether it would control natural tuber infections. This substance and its salts have been shown to be actively fungistatic by Eckert and Kolbezen³, who used them chiefly against fungal rots of citrus fruits. Sec-butylamine is a colourless liquid with an ammoniacal odour, easily vaporized (boiling point 63° C), miscible with water and most organic solvents. It is a moderately toxic substance, the toxicity being due primarily to its strong alkalinity, but effects are minimized by both dilution and neutralization.

In the first tests 38 kg of freshly lifted naturally infected tubers of several cultivars were fumigated with different doses of gaseous sec-butylamine in a 400 l. steel fumigation chamber fitted with an external circulatory system to assist application and distribution of the gas. The potatoes were exposed to the gas for about 2 h during which most of it was absorbed.

* Trace, 1-10 pustules per tuber; slight, up to 1/10 of tuber surface covered; moderate, between 1/10 and 1/4 surface covered; severe, more than 1/4 surface covered.

The treated and untreated tubers were placed in wooden sprouting trays and stored over winter. All the tubers were examined periodically until the end of March for the appearance of gangrene lesions, and skin spot was assessed at the end of the storage period by Boyd's method⁴ using fifty tubers. Results of some of the experiments are shown in Tables 1 and 2. Because the treatments showed such promising control of both diseases with no evidence of tuber phytotoxicity we built a large experimental fumigation chamber to hold 5 tons of tubers, fitted with a forced draught gas recirculation system incorporating an apparatus capable of vaporizing the required amount of *sec*-butylamine in approximately 40 min. Tubers were fumigated within 48 h of lifting with a dose of 200 mg/kg. Analyses of gas samples drawn through tubes ending at different positions in the bulk showed that even distribution of the gas throughout the air spaces between tubers was only obtained slowly. During the application considerable condensation and adsorption took place on the lower layers of tubers, and this was apparently followed by processes such as evaporation, desorption and further adsorption throughout the bulk when recirculation of the mixture of air and gas was continued after all the fumigant was applied. Residue analyses on samples taken from various positions in the bulk indicated that good distribution of the fumigant on tubers had been achieved after recirculation for a further 2 h. After fumigation 1/2 ton bulks made up of tubers taken from different positions in the chamber were stored under straw in a shed until February, when they were sorted and assessed for rot diseases. The healthy material was then boxed. Further disease assessments were made in early April, and the visual diagnoses checked by isolation of fungi from representative tuber samples. For controls 1/2 ton untreated lots from the same consignment were stored similarly. Results of four experiments are shown in Tables 3 and 4.

Table 3. EFFECT OF BULK TREATMENT WITH *sec*-BUTYLAMINE ON THE INCIDENCE OF GANGRENE

Cultivar	Treatment	No. of tubers examined	Per cent gangrene
Majestic	200 mg/kg	1,328	0.2
	Nil	1,376	4.1
Redskin	200 mg/kg	567	0.7
	Nil	552	88.6

Table 4. EFFECT OF BULK TREATMENT WITH *sec*-BUTYLAMINE ON THE INCIDENCE OF SKIN SPOT

Cultivar	Treatment	Percentage of tubers affected in each category				Skin cover score			
		Free	Some	All	None	Trace	Slight	Moderate	Severe
King Edward	200 mg/kg	100	0	0	100	0	0	0	0
	Nil	13	56	31	0	20	70	9	1
Majestic	200 mg/kg	100	0	0	98	2	0	0	0
	Nil	14	76	10	2	32	46	18	2

As well as a visual examination for skin spot, eye plug samples from the King Edward stock were incubated in moist chambers and examined microscopically for the development of *O. pustulans*⁵, which was not detected. The tuber diseases dry rot (caused by *Fusarium caeruleum*) and blight (caused by *Phytophthora infestans*) were not controlled, but the effect of fumigation with *sec*-butylamine on other diseases has not yet been investigated.

Sec-butylamine in a dose of 200 mg/kg had no phytotoxic effect on undamaged tubers although badly skinned areas, especially on immature tubers, could be discoloured. Extensive skin damage and complete death of eyes were caused by a dose between 1,000 and 5,000 mg/kg. Preliminary results of field trials showed that treatment of tubers with *sec*-butylamine at 200 mg/kg had no adverse effect on plant growth or yield. Experiments are continuing on various aspects of the treatment including determination of residues in treated tubers and in crops grown from treated tubers. Studies are also being made on the physical processes operating in fumigating bulks of tubers with *sec*-butylamine. United Kingdom and Irish patents have been applied for.

Phenolase Inhibitor from Cultures of *Penicillium expansum* which may Play a Part in Fruit Rotting

PREVIOUS work in this laboratory¹ has shown that the light colour of apples infected with *Penicillium expansum* ("blue-mould") is due to the inhibition by the fungus of the fruit's normal enzymatic browning system. A positive feedback system operates whereby the fungal pectolytic enzymes modify the apple's phenolics to yield inhibitors of apple phenolase (*o*-diphenol oxidase) and the associated biochemical defence system. But the problems of the initial establishment of fungal growth remain and I wish to report evidence that the fungus secretes its own phenolase inhibitor until it is sufficiently established to allow the second, major positive feedback system to take over.

Cultures of *P. expansum* were grown as mats on a yeast-malt broth² or on Czapek-Dox medium at 26° C. The culture medium was sampled aseptically at suitable intervals and tested for its ability to inhibit the oxidation of catechol by a phenolase preparation from apple chloroplasts³. In yeast-malt medium the concentration of inhibitor was maximum between 36 and 48 h of growth and had diminished to zero after 96 h when the mycelial mat had begun to sporulate. By contrast, cultures on Czapek-Dox medium grew more weakly and formed less inhibitor even after incubation for 14-16 days.

The biochemical properties of this phenolase inhibitor, which I call "expansin", were investigated using the original culture medium, or an ethereal extract prepared by extraction of the broth with diethyl ether followed by a single wash with a saturated solution of NaHCO₃. Dixon's method showed that "expansin" competitively inhibited the oxidation of chlorogenic acid, catechin and catechol by particulate phenolase preparations from apples and tobacco leaf, whereas it had no effect on a laccase (*p*-diphenol oxidase) preparation from *Glomerella*

*cingulata*⁵. The degree of inhibition increased by up to 50 per cent if the extract was pre-incubated with the enzyme for longer than 40 min before addition of substrate. A similar effect of time of pre-incubation was observed by Harel *et al.*⁶ for a phenolase inhibitor extracted from the mycelium of *Dactylium dendroides*⁷.

Chemical investigations of expansin were hampered by its instability in aqueous solution and the very low concentrations present in the culture medium. Inhibitory activity was destroyed by boiling or by alkalis stronger than NaHCO_3 . The crude ethereal extract was examined by chromatography and electrophoresis on thin-layers. The bands were scraped from the dried thin-layer chromatography (TLC) plates into tubes containing buffer (0.1 M phosphate, pH 5.0) and phenolase preparation in a final volume of 5 ml. Substrate (10 μmoles of catechol + 50 μmoles of glycine) was added 40 min later and the tubes were incubated, with shaking, at 30°C. If expansin was present the reaction mixture remained colourless while control tubes turned red-brown. Expansin had R_f values of 45–50 in 2 per cent (v/v) acetic acid and 90–95 in a mixture of benzene, acetic acid, water (125:72:3) or a mixture of *n*-butanol, acetic acid and water (12:3:5). These zones did not correspond with areas of fluorescence on the TLC plates, nor did they react when tested with various chromogenic spray reagents, probably because of the low concentration present. Expansin is probably neutral, for it did not migrate appreciably in an electric field (20 V/cm, pH 2.0) nor was it absorbed by ion-exchange resins. Chromatography on columns (42 x 2 cm) of 'Sephadex G-15' with water as the eluant suggested that expansin had a relatively low molecular weight. The ultraviolet spectra of the fractions which contained inhibitor showed maximum absorption at 280–290 nm. Attempts to purify further these fractions from the 'Sephadex' were unsuccessful. Comparative tests with several known metabolites from *Penicillium* sp.⁸, such as patulin, gentisaldehyde, gentisic acid, 6-methyl-salicylic acid and *p*-hydroxybenzoic acid confirmed that these compounds were devoid of inhibitor activity at concentrations up to 0.01 M.

Harel and his collaborators⁶ have reported that the fungus *D. dendroides* secretes a small peptide which inhibits apple phenolase⁶ and galactose oxidase⁷, both enzymes which contain copper, by reacting with the prosthetic group. But the evidence is that expansin is not a peptide and, furthermore, it acts by competition with the substrate.

The findings are interesting from the point of view of the biochemistry of the relationship between host and parasite, and could explain the mechanism whereby *P. expansum* overcomes the apple's defence mechanisms during the earliest stages of infection and mycelial growth. If expansin is formed *in vivo* it could suppress enzymatic browning until the fungal extracellular pectolytic enzymes have developed and modified the phenolics of the apple to yield phenolase inhibitors such as *p*-coumaric acid and ferulic acid¹.

I thank Drs J. D. Bu'Lock and S. W. Tanenbaum for 6-methyl-salicylic acid and Miss Barbara Donnithorne for technical assistance.

Initiation of Flowering on First Year Cuttings of *Metasequoia glyptostroboides* Hu and Cheng

AFTER its discovery in the interior of China at latitude 30° N in 1941, *Metasequoia glyptostroboides* was introduced to Britain in 1948, and has been propagated by cuttings and established in botanical gardens and parks throughout the country. Although there are now specimens up to 16 m high, flowering has been confined to occasional female cones, which in the absence of pollen have not produced viable seeds¹. Male cones do not seem to have been recorded here² although both seedlings and cuttings growing in the Crimea at 45° N have produced them after an interval of 7 yr³. Flowers of both sexes have been induced in Japan by strangulation⁴ and by treatment with gibberellic acid^{5–7}.

Both male and female cones have now been initiated on 1 yr old cuttings grown in a greenhouse in Edinburgh. In September 1968, shoots with vegetative buds were taken from a tree aged about 14 yr from planting (probably itself a cutting), treated with 'Seradix' No. 2 rooting powder and placed under mist. The rooted cuttings were potted in December 1968, and six were kept in partially controlled greenhouse conditions for observation. The male cones were first seen on November 22, 1969, partially emerging from buds on one plant, and male initials have since been found on two more plants. Eleven male cones have been identified, together with twenty-eight possible flower buds, all occupying terminal positions on branchlets which are usually budless and deciduous, both the simple and the branched type (Fig. 1). In plants growing outside, such shoots normally cease development and fall off by late November, but they were retained up to 3 months longer on the plants in the greenhouse. Most of the fertile branchlets eventually abscised, but two were retained for 6 weeks in a cold room at 6°C. These chilled cones emerged fully (Fig. 2), and have shed pollen freely. Five female cones emerged at the same time, some from lateral buds on the main stem, and some in a similar position to the male (Fig. 3). These have now been self-pollinated, and have begun to enlarge.

It seems likely that this early initiation of flowering may have been encouraged by the long period in warm conditions. The plants were not chilled during the winter of 1968–69, and they flushed in late March 1969 and rapidly completed extension of their terminal shoots. During September and October, many lateral shoots extended, providing the loci at which flowers could be initiated.

Although these investigations are at a very early stage, they are interesting for several reasons. Production of

Fig. 1. *Metasequoia* cutting No. 6 on December 1, 1969. Two male cones can be seen partially emerging without chilling (bottom of picture). Above them, two shorter fertile branchlets can be seen, whose buds emerged after chilling (Fig. 2).

Fig. 2. The same cutting as in Fig. 1. March 6, 1970, two days before the two male cones began to shed pollen. The length of a cone is about 4 mm, and of a leafless "stalk" about 3 mm. Each cone scale bears two or three abaxial pollen sacs.

Fig. 3. The top of the same cutting as in Fig. 1, on March 6, 1970. There are two female cones at the ends of branchlets, and three in lateral positions on the main stem. There are vegetative buds below and near the apex. The length of female cones is 4–6 mm on leafy "stalks" which subsequently extended rapidly.

pollen may make it possible to produce fertile seed for the first time in Britain, and also to cross selected clones with one another to raise improved planting stock. Such genetical work is always facilitated when flowering can be controlled, but the study of the reproductive physiology of forest trees has been hampered by the technical problems of experimenting with large plants. *Metasequoia* cuttings such as these, which were only 30 cm high, clonal, and growing well in 5 inch pots, would provide almost ideal material for growth-room investigations into the effects of day length, temperature, hormones or other treatments on flower initiation. Similarly, studies of flower bud development, pollination and seed production would be possible in controlled environments, and we may be able to deal with the juvenile,

purely vegetative phase in coniferous trees, for seedlings of this species seem to be capable of producing female cones before reaching an unmanageable size³.

I thank the University of Edinburgh for greenhouse and laboratory facilities, Mr C. Crawford for photography, and Mr J. Howarth and Mr D. S. Coutts for their assistance.

Biological Control of Decay Fungi in Wood by Competition for Non-structural Carbohydrates

HYPHA of fungi that decay wood spread rapidly through their host substrate before any significant loss of weight is detectable¹. Indeed, the rate of advance of *Fomes annosus* over or through red pine was identical with its growth rate over malt-agar plates² even though fungi that decay wood develop more slowly on cellulose than on simple sugars³. Glucose stimulates growth over wood⁴, and laboratory cultures provided with a choice of cellulose or a simple carbon source preferentially utilize the latter^{5,6}, for enzymes that hydrolyse cellulose are generally only produced when growth is restricted⁷. These data suggest, as expected, that fungi initially colonize wood chiefly by utilizing non-structural carbohydrates. Such materials would include simple sugars which have been identified in the sapwood of both hardwoods⁸ and softwoods⁹ and which in the latter account for 0.03 to 0.8 per cent of the dry weight; figures for the inner bark are, of course, considerably higher. Polysaccharides such as starch may also be utilized rapidly: ray cells often provide entrance for invading hyphae and starch reserves of these cells were quickly exhausted, for example, during early decay of sweetgum sapwood by *Poria monticola*¹⁰. Traces of polysaccharides grouped with holo-cellulose may also be readily available and thus utilized early in the decay process¹¹.

During natural decay of wood, many ecological factors determine the course and succession of fungal colonization¹², but in conditions that are favourable for many wood-inhabiting fungi, the success of a fungus as a primary wood saprophyte may largely depend on its ability to spread rapidly through wood by utilizing non-structural carbohydrates. A guide to this ability might be obtained by using similar conditions to assess the rate of development of the wood-inhabiting fungus on simple sugars. *Trichoderma viride*, for example, often colonizes wood, and although it can decompose cellulose, its ability to utilize structural polysaccharides of wood is very limited^{13–15}; it also grows very rapidly over malt-agar plates at 20–30° C (ref. 16). *T. viride* may retard the development of other fungi by producing the antibiotics gliotoxin or viridin, although attempts to demonstrate this with plate cultures have been unsuccessful¹⁶. Tests with liquid cultures indicated that these antibiotics may not be produced by *T. viride* but by the closely related *Gliocladium*¹⁷. Perhaps *T. viride* retards colonization by other fungi by rapidly removing the non-structural carbohydrates of wood which seem to be necessary for rapid hyphal progression. A similar conclusion explained the antagonism of soil bacteria towards *Fusarium oxysporum*

Table 1. PERCENTAGE LOSS OF WEIGHT OF OVEN-DRIED BLOCKS OF BIRCH SAPWOOD DURING 4 MONTHS INCUBATION WITH ONE OR TWO FUNGI AT 27° C

	<i>T. viride</i>	<i>G. viride</i>	C134	None
<i>P. adustus</i>	16	29	48, 4*	37
<i>P. hirsutus</i>	1	11	—	64
<i>P. versicolor</i>	3	33	—	82
None	2	2	4	—

Blocks (2 × 2 × 2 cm) containing 45 per cent moisture were placed on the surface of soil containing 40 per cent moisture. Inocula were grown on birch-wood slips on 2 per cent malt-agar; two slips were then placed underneath each wood block. When two fungi were used they were allowed to develop on separate slips. Values are an average of four replicates.

* Inoculation with *P. adustus* delayed for 1 month.

f. sp. *cubense*, in which inhibition of fungal growth was not due to antibiotics and only occurred when nutrient concentrations were low¹⁸.

To test this hypothesis we evaluated fungal interaction in birch (*Betula papyrifera*). We used common isolates from decaying birch wood including (together with their growth rates over malt-agar plates at 27° C) *Polyporus adustus* (17 mm per day), *Polyporus hirsutus* (13 mm per day) and *Polyporus versicolor* (13 mm per day), all of which cause a typical white rot; C134 (2 mm per day), an unidentified, non-sporulating, apparently non-destructive fungus, and *T. viride* (27 mm per day). *Glaciadium viride* (22 mm per day) isolated from decaying aspen wood was also used. Clear zones of inhibited growth due to the production of antibiotics could not be detected in malt-agar plate cultures of any of the three species of *Polyporus* paired with either C134, *T. viride* or *G. viride*; the basidiomycetes often overgrew the other fungus.

The same pairs of fungi were used to inoculate blocks of birch sapwood in a soil-block test; results are shown in Table 1. *T. viride*, the fastest growing fungus on malt-agar, provided the best protection from decay by the basidiomycetes. The possible production of antibiotics by *G. viride* seemed to be of minor ecological importance and its comparative ability to prevent decay was more closely correlated with its rate of growth over malt-agar. C134 provided no protection and even increased decay by *P. adustus*, demonstrating growth synergism¹⁹, unless the former was developing alone as the primary saprophyte. Of the basidiomycetes, *P. adustus* caused the least loss of weight when used alone but was the most successful basidiomycete in these competitive soil-block trials and was also the fastest growing basidiomycete over malt-agar. In all experiments, blocks that had lost a little weight were sound and unstained after incubation. Rotted blocks containing two fungi were decayed only on the side inhabited by the basidiomycete.

Results of field trials involving random infection of birch logs further supported the hypothesis. Table 2 shows that immediate inoculation with *T. viride* afforded excellent protection to the logs when stored for 7 months, even when followed by attempts to infect the logs with *P. adustus* 2 weeks after inoculation. By contrast, the slower growing C134 was totally inadequate. If inoculation

with *T. viride* was delayed for 4 days other fungi, generally those which grow most rapidly over malt-agar plates at ambient temperatures, rapidly infiltrated the wood, demonstrating the speed of this initial process of colonization. Similarly, if *P. adustus* was used for the immediate inoculation it colonized the logs almost to the total exclusion of other fungi, but if inoculation was delayed for 2 weeks any advantage was lost.

The results are of practical significance in attempts to protect wood from decay. In addition, the permeability of wood to preservatives is considerably enhanced after colonization by *T. viride*²⁰. Although *T. viride* seems to approach the practical ideal of a scavenging cellulolytic fungus which can rapidly remove non-structural carbohydrates from wood without substantially altering its mechanical properties or physical appearance, comprehensive screening programmes will doubtless reveal better organisms for this purpose, particularly in different environmental conditions.

Export of Photosynthate Affected when Leaves are Pretreated with Growth Substances

SEVERAL investigators have shown that cytokinins are strong mobilizing agents¹⁻³. For example, a spot of cytokinin on a leaf can attract such substances as amino-acids from adjacent untreated tissues, and treatment of fruits^{4,5}, shoot tips⁶, or expanded leaves⁷ increases movement of photosynthate into the treated area. Gibberellic acid also enhances movement of assimilates into the treated area, but the growth retardant CCC ((2-chloro-ethyl)-trimethylammonium chloride) causes a decrease in the mobilizing power of the treated area^{4,6}. We are not aware, however, that leaves on intact plants have ever been pretreated with growth regulators to study the effect on the export of photosynthate from the treated leaves.

Rootings of *Vitis vinifera* L. 'Thompson Seedless' were grown in 'Sponge Rok' in 1 gallon containers. Hoagland No. 1 solution at half strength was used to irrigate the plants⁸, which were used when the shoots were 12-14 inches long. In each experiment, young, fully expanded leaves which were exporting photosynthate upwards in

Table 2. PRINCIPAL FUNGAL ISOLATES FROM BIRCH LOGS STORED IN OTTAWA

Control (sterile water immediately)	17	0	109	19	43

The fresh sound birch logs were 120 cm long and 15-25 cm in diameter. A disk, 8 cm thick, was sawn from each end at the start of the experiment in early May. After inoculation by spraying the ends with a mycelial and/or spore suspension the ends were covered with polythene for 3 days. After 7 months a fitch 8 cm thick was sawn from the centre of each log and a row of six isolations attempted every 15-20 cm along each side by placing the removed chip on 2 per cent malt-agar.

* *P. hirsutus* was only found in the control (30 isolates).

the shoot were dipped momentarily into a solution containing a growth regulator. After 3 h the treated leaves were exposed for 30 min to $^{14}\text{CO}_2$ from labelled barium carbonate (0.5 mg) with a specific activity of 0.05 mc./mg. The label was applied to the leaves according to the

method of Hale and Weaver⁹. Six hours after the beginning of exposure the shoots were collected, mounted and autoradiographed according to the method of Yamaguchi and Crafts¹⁰. The X-ray film was exposed to the mounts for 7 days. Three replicate shoots were used in each treatment.

In one experiment the leaves were dipped in benzyladenine at 4,000 p.p.m. Corresponding leaves on the control shoots were exposed to $^{14}\text{CO}_2$ without prior treatment with benzyladenine. In the controls, the photosynthate was exported from the leaves and, after entering the stem, moved acropetally. Only a small amount of assimilate was exported from the treated leaves. As a result of treatment with benzyladenine, the fully expanded leaves, which normally export photosynthate to the shoot tips, had become strong "sinks" for assimilate, so that little export occurred. When 1,000 p.p.m. of gibberellic acid was used instead of benzyladenine, results were similar.

When 4,000 p.p.m. of the plant growth retardant (2-chloroethyl)trimethylammonium chloride (CCC) was used, photosynthate moved out of the treated leaves at the same rate as from the untreated leaves. In both cases, movement in the stem was upward. The export of photosynthate out of the leaves treated with CCC is in agreement with earlier findings that this compound tends to counteract the mobilizing power of the leaves as a "sink"⁶. Growth regulators have been shown to have no marked effect on CO_2 fixation in plants¹¹, so this factor can be eliminated in the explanation of our results.

This investigation was supported in part by a grant from the US National Science Foundation.

Note that there was very little export of labelled carbon dioxide from the treated leaf.

Xanthoxin, a New Naturally Occurring Plant Growth Inhibitor

We have extracted a neutral growth inhibitor from the seedlings of dwarf bean (*Phaseolus vulgaris* cultivar 'Canadian Wonder') and wheat (*Triticum vulgare* cultivar 'Hybrid' 46). Comparison of chemical, chromatographic and bioassay data has shown it to be a mixture of two isomeric compounds which we have characterized as products of the photo-oxidation of violaxanthin¹, a common plant xanthophyll. They are the highly active 5-(1',2'-epoxy-4'-hydroxy-2',6',6'-trimethyl-1'-cyclohexyl) 3-methyl-*cis,trans*-2,4-pentadienal (I) and the less active *trans,trans* isomer (II). The name xanthoxin is now proposed for the inhibitor, the activity of which in the *cis,trans* configuration is comparable with the known naturally occurring inhibitor abscisic acid (ABA) in several tests.

Bean seedlings were grown on 'Vermiculite' in a 16 h photoperiod (800 lumens/foot² from natural daylight fluorescent tubes) at 25° C (night temperature 24° C). Eight day old shoots (250 g fresh weight) were frozen in ether (1.5 l.) at -20° C, crushed and maintained at 3° C in darkness for a 24 h extraction period. All subsequent operations were carried out in a shaded laboratory. The ether extract was decanted from the tissue and shaken with 2 per cent sodium bicarbonate solution (twice) and water to remove acids. The ether was removed at reduced pressure and the extract was redissolved in light petroleum (60°-80° C). This solution was partitioned with an equal volume of 80 per cent aqueous methanol, which was then adjusted to 50 per cent by the addition of water, and the xanthophylls were largely removed by further partitioning with light petroleum. The methanol was distilled from the extract, and, after the addition of sodium sulphate, the aqueous solution was re-extracted with ether.

Further purification of this ether extract was carried out on a column (18 mm bore) containing 100 mesh silicic acid powder (20 g), using a mixture of benzene and ethyl acetate (2:1) as solvent and collecting 10 ml. fractions. Each of these forty fractions was assayed for plant growth inhibitors in the wheat coleoptile section test² (using 2 ml. aliquots) and the cress seed germination test² (using 0.2 ml. aliquots). The results of these tests (Fig. 1) showed that the principal inhibitor was present in fractions 21-27. These fractions were combined and two aliquots (4.0 and 0.4 ml.) were streaked onto a chromatoplate ('Kieselgel GF 254', 20 × 20 cm, 0.2 mm thick) with a mixture of the violaxanthin photoproducts (I) and (II) as a reference. After developing three times in light petroleum-acetone (3:1), 20 equal 7.5 mm strips of silica gel were removed from each of the separated extracts, and eluted with methanol (1 ml.). The eluates from the 4 ml. aliquot were assayed in the coleoptile section test, and those from the smaller aliquot in the germination test. In both of these tests there was a single zone of inhibition (R_F 0.5-0.6) which corresponded exactly with the "reference spot" (revealed by ultra-violet quenching). A similar chromatogram of the combined inhibitory column fractions (2 ml. aliquot), when sprayed with 2,4-dinitrophenylhydrazine reagent, developed a strong orange spot which was the same colour as that given by the violaxanthin oxidation product and with the same R_F value.

The remaining inhibitory fractions were concentrated and acetylated by treatment with acetic anhydride in the presence of pyridine. The chromatographic procedures we have described were repeated using this acetylated product and a mixture of the acetates of (I) and (II). In these tests, inhibition was again shown to occur within the region of the chromatogram which also gave an

Fig. 2. Gas liquid chromatograms of (a) acetylated violaxanthin photoproducts; (b) acetylated bean tissue extract; (c) a mixture of (a) and (b). Peaks produced by the acetates of the *cis,trans* (I) and *trans,trans* (II) isomers are indicated.

orange spot when sprayed with 2,4-dinitrophenylhydrazine reagent, and at the same R_F as the authentic acetates (about 0.8).

Further evidence for the identity of the dwarf bean inhibitor with the violaxanthin photoproducts was obtained from a comparison of their acetates by gas liquid chromatography. We used a Pye series 104 chromatograph and a 150 cm column of 1.5 per cent XE-60 on 'Gaschrom-Q' at 187° C (50 ml./min flow rate of nitrogen) was used to separate the acetates of the isomers. The acetylated bean extract contained both *cis,trans* and *trans,trans* isomers with the latter predominating (Fig. 2).

The possibility that the bean inhibitor had been formed from xanthophylls during the purification of the plant extracts was investigated separately. Two batches of dwarf bean seedlings (70 g fresh weight each) were extracted with ether. Violaxanthin and neoxanthin, the two xanthophylls which have previously been shown to produce inhibitor on illumination^{3,4}, were also obtained from bean seedlings (350 g fresh weight) and added to one of the extracts. The precise purification procedures we have described were then carried out on the "bean extract" and "bean extract plus pigment". Bioassay tests on these extracts showed conclusively that the five-fold increase in the quantities of violaxanthin and neoxanthin present had not altered the concentration of inhibitor.

Bean seedling extract was also used to investigate the effect of temperature and light intensity during purification. It was shown that an extract processed in a cold room (3° C) with the minimum of red light contained the same quantity of inhibitor as a similar extract purified in normal laboratory conditions. These results indicate that the bean inhibitor is present in the plant tissues and is not formed from pigments during the extraction and isolation processes used.

These extraction, purification and assay methods were used with wheat seedlings which had been grown in the same environmental conditions as those described for dwarf beans. When extracts were chromatographed on silicic acid and the fractions assayed for growth inhibitors, histograms similar to those in Fig. 1 were obtained. Furthermore, examination of the principal inhibitory fractions, as previously described, gave results similar to those obtained with bean seedlings. We therefore conclude that xanthoxin occurs in both normal shoots of dwarf bean and leaves of young wheat seedlings.

Xanthoxin is thus a highly active growth inhibitor occurring naturally in certain plant tissues, and we consider it likely that the compound is formed *in vivo* by the oxidation of xanthophylls. The metabolism of xanthoxin and its possible relationship with (+)-ABA are being investigated in this laboratory.

We thank Professor R. L. Wain for advice and encouragement, and Mr R. P. Townsend and Mr P. Cozens

Life Cycle of *Eimeria stiedae*

KNOWLEDGE of the early development of *Eimeria stiedae*, before the appearance of trophozoites in the liver of its rabbit host, is remarkably scanty. After initial penetration of the duodenal epithelium by the sporozoites, the earliest observation of trophozoite formation has been 72 h after infection. The route of migration of the sporozoites during this period has long been a subject for speculation, and the most favoured theory has been passage to the liver from the mesenteric lymph node in the portal blood. Slater, Quisenberry and Fitzgerald¹ gave support to this theory by reporting the presence of sporozoites in the mucosa after 5–9 h, free and in monocytes in the mesenteric lymph nodes and in monocytes in the peripheral blood 16–20 h after infection.

One of the principal technical difficulties in the study of specific coccidia has been the difficulty in keeping experimental animals free of extraneous coccidial infection. The work described in this preliminary communication has been carried out using specific pathogen free (SPF) animals which were entirely free from coccidia, and maintained during experiment in plastic film isolators similar to those used for maintaining gnotobiotic animals. The use of this type of animal and equipment has made possible a different approach to the study of *E. stiedae*.

Previous research was directed largely towards the demonstration of the sporozoites in the tissues by direct staining or labelling. I have tried to trace the spread of the organisms by an indirect method of tissue inoculation from experimentally infected donor rabbits into non-infected recipient rabbits. By maintaining their SPF condition, the recipients were then used as indicators for the presence of viable sporozoites in tissues where they had not previously been demonstrated by other techniques.

Donor rabbits dosed with $2-4 \times 10^6$ sporulated *E. stiedae* oocysts by stomach tube were killed 12, 24 and 48 h after infection, and samples of lymph node and bone marrow were aseptically removed. From the donor rabbits culled after 48 h, liver and blood buffy layer, axillary lymph node and washings from the coelomic cavity were also taken. These tissues were homogenized and injected intravenously into 8 week old recipient rabbits previously sedated with 5 mg of promazine hydrochloride.

Recipients were examined daily for signs of infection, and faecal samples were taken for flotation tests. Animals were killed at the first appearance of oocysts in the faeces or 16–20 days after inoculation if there were no signs of infection.

The results showed that viable sporozoites were present in the mesenteric lymph node after 12 h, in bone marrow after 24 h and in liver and buffy layer after 48 h. Infection could not be induced from the axillary lymph node, washings from the coelomic cavity or from control donors.

Liver tissue taken after 48 h produced severe coccidiosis in test animals. But the apparent presence of sporozoites in blood and bone marrow after 24 h indicates a widespread distribution of organisms with possible involvement of the liver much earlier in infection than previously appreciated. Viable organisms were present in the mesenteric

lymph node as early as 12 h after infection, producing mild hepatic lesions in the test rabbits. The increasing severity of lesions with tissue taken at 24 and 48 h suggests that there may be a steady accumulation of organisms in this tissue.

It is hoped that further tests and quantitative studies on tissue taken at different time intervals after oral infection will help to further clarify the situation regarding the spread of sporozoites during the first 72 h after infection.

Respiration, Growth and Maintenance in Plants

THE dependence of plant respiration on photosynthesis and dry weight interests the crop scientist, and recently McCree¹, in order to account for his data on white clover, put forward the following simple equation to describe whole plant behaviour

$$R_d = kP_g' + cW \quad (1)$$

where R_d is the dark respiration rate, W is the plant dry weight, and k and c are constants. P_g' is a gross photosynthetic rate which is calculated by using

$$P_g' = P_n + R_d$$

where P_n is the net photosynthetic rate. In this communication equation (1) is derived theoretically using a straightforward extension of Pirt's discussion of yield and maintenance in bacterial cultures². The derivation gives a better understanding of the role of the constants k and c in McCree's equation. The relevance of dark and light respiration to the following analysis (where this distinction is at first ignored) and to McCree's equation is discussed later.

It will be assumed that in a time interval Δt the amount of substrate Δs generated by photosynthesis is $P_g \Delta t$, where P_g is the gross photosynthetic rate, so that

$$\Delta s = P_g \Delta t \quad (2)$$

In a steady state, this increment of substrate Δs must be completely utilized during time Δt . It will be assumed that this substrate has only two uses—maintenance and growth. Thus a part of the substrate (Δs_m) is respired for the provision of maintenance energy, and a part (Δs_g) is used for growth

$$\Delta s = \Delta s_m + \Delta s_g \quad (3)$$

All the substrate appearing in the term Δs_m is respired, whereas only part of the substrate in Δs_g is respired, the rest being turned into plant material. It will be supposed that Δs_g may be partitioned

$$\Delta s_g = \Delta s_r + \Delta s_t \quad (4)$$

where Δs_r is completely respired, and the resulting energy is used to transform Δs_t into plant material (this term includes both structural and storage components) without loss of mass; substrate and plant material are measured in units of CO_2 equivalents. The term, yield (Y), will be used here in the microbiological sense to mean increase in mass in plant material per unit mass of substrate used. The yield of the process of constructive growth (Y_G) is then given by

$$Y_G = \frac{\Delta s_t}{\Delta s_r + \Delta s_t} \quad (5)$$

The observed yield (Y) is (compare ref. 2, equation 1)

$$Y = \frac{\Delta s_t}{\Delta s_m + \Delta s_r + \Delta s_t} \quad (6)$$

From equations (2), (3) and (4)

$$P_g = \frac{\Delta s_m}{\Delta t} + \frac{\Delta s_r}{\Delta t} + \frac{\Delta s_t}{\Delta t} \quad (7)$$

and from equation (5)

$$\frac{\Delta s_t}{\Delta t} = \left(\frac{Y_G}{1 - Y_G} \right) \frac{\Delta s_r}{\Delta t} \quad (8)$$

The maintenance requirement may be expressed in terms of substrate consumed per unit of plant material per unit time. Following Pirt² the maintenance coefficient m is defined by

$$\frac{\Delta s_m}{\Delta t} = mW \quad (9)$$

The respiration rate is given by

$$R = \frac{\Delta s_m}{\Delta t} + \frac{\Delta s_r}{\Delta t} \quad (10)$$

and applying equations (7), (8) and (9) to equation (10)

$$R = (1 - Y_G)P_g + mY_GW \quad (11)$$

which is of the form of McCree's equation.

Another useful form of this equation can be obtained by rewriting it in terms of net photosynthetic rate, P_n . Using

$$P_g = P_n + R \quad (12)$$

one obtains

$$R = \left(\frac{1 - Y_G}{Y_G} \right) P_n + mW \quad (13)$$

The formal relation between the yield constants Y and Y_G is exactly the same in plants as in bacteria (ref. 2, equation 6). Defining the relative growth rate μ by

$$\mu = \frac{1}{W} \frac{\Delta s_t}{\Delta t} \quad (14)$$

then from equations (5) and (6)

$$\frac{1}{Y} = \frac{1}{Y_G} + \frac{m}{\mu}$$

It can easily be shown that the relative growth rate for plants is then given by equations (14), (7), (8) and (9)

$$\mu = Y_G(P_g - mW)/W$$

Rates of respiration in the light are usually greater than in the dark, and it is assumed here that respiration in the light consists of light and dark components, the dark component being unaltered by light. If the light component of respiration is zero then $R = R_d$, $P_g = P_g'$ and equation (11) becomes identical to McCree's equation. If the light respiration is simply due to cycling of CO_2 into and out of the plant with no useful products, then for the present purpose it can be ignored. R_d is used in equations (11), (12) and (13), again giving an identity between McCree's equation and equation (11). If light respiration results from substrate utilization for constructive growth, then this process will probably have a different (lower) yield than the constructive growth component of dark respiration. However, in order to extend the above analysis to cover this case, it is simplest to assume that both components have the same yield, and examine the consequences of this assumption. The respiration rate R (which is really an average respiration rate over time interval Δt) now includes both the light and dark components

$$R = R_d + R_l$$

so that

$$P_g = P_g' + R_l$$

R_l is the light-dependent component of the respiration. If these two relations are put into equation (11), then

$$R_d = (1 - Y_G)P_g' - Y_G R_l + mY_GW \quad (15)$$

This equation can be written in the same form as McCree's equation if it is assumed that the light respiration rate is proportional to the gross photosynthetic rate:

$$R_l = \alpha P_g' \quad (16)$$

which implies that $P_g = (1 + \alpha)P_g'$. Putting equation (16) into (15) gives

$$R_d = [1 - Y_G(1 + \alpha)]P_g' + mY_GW \quad (17)$$

This expression suggests how the role of light respiration might tentatively be assessed from experiment. A direct measurement of light respiration will make it possible to calculate α from equation (16); another value of α can be obtained from a McCree-type of experiment (using equation (17)) if the yield constant Y_G can be measured by some independent means (carbohydrate utilization, for instance); if α from equation (17) is, say, a half of α from equation (16) this indicates that only a half of light respiration results from processes useful to the plant.

McCree¹ found for white clover that $k = 0.25$ and $c = 0.015 \text{ g CO}_2 \text{ day}^{-1}$ (gCO_2 equivalent of dry weight)⁻¹. Applying equation (17), this gives $Y_G(1 + \alpha) = 0.75$. Measured values of yield listed by Warren Wilson (Table 4, ref. 3) are close to 0.75, but are usually a little lower; this possibly indicates (this comparison must be made with caution because of differences in units used) that α is greater than zero and that light respiration contributes significantly to growth. Taking $\alpha = 0$, and using McCree's value for c , the maintenance coefficient m becomes $0.020 \text{ gCO}_2 \text{ day}^{-1}$ (gCO_2 equivalent of dry weight)⁻¹. This compares with a value of about 2 (in the same units) for *Aerobacter aerogenes* growing aerobically on glycerol². This ratio of about 100 between the maintenance coefficients of white clover and *Aerobacter* is reflected by similar differences in growth rate and protein turnover rate between higher plants and microorganisms.

Although this analysis has been applied to the whole plant, the same considerations describe a part of a plant if gross photosynthetic rate is replaced by the rate of supply of substrate.

I thank Dr J. Warren Wilson for helpful discussions, and Drs R. G. Hurd and B. Acock for useful criticism.

Potential Quasi-energy and Energetically Optimal Size in Living Organisms

BIOENERGETICS is concerned with the relationship between the rate of energy exchange by an organism and the other parameters of its body. Perhaps the best known findings are, first, that the total heat production $Q(m)$ increases with increasing body mass according to equation (1) (refs. 1 and 2).

$$Q(m) \approx am^b \quad (1)$$

Fig. 1. Total heat production $Q(m)$, specific heat production $q(m)$, and auxiliary function $P(m)$ in shrews.

where m is the body mass, a is the so-called energy level of the organism^{2,3} and b never exceeds 1.00. Second, the specific heat production decreases with increasing body weight according to equation (2) (Fig. 1).

$$q(m) = Q(m) \approx am^{b-1} \quad (2)$$

Several authors have emphasized that in order really to understand evolution it is necessary to know the relationship between the functions² $Q(m)$ and $q(m)$. An attempt at such an analysis is outlined here.

Consider what we shall call the quasi-energy $H(m)$ of an organism of mass m , defined as the product of $Q(m)$ and $q(m)$, that is,

$$H(m) = Q(m) \cdot q(m) \quad (3)$$

When calculated for shrews (Fig. 2) $H(m)$ shows features which are characteristic of potential energy curves, for example, a "potential well" and a "potential barrier", and we feel that these features are of biological significance. Experimental data⁵ suggest that the crucial stages in the life cycle of the shrew, that is survival in winter and the reproductive period in spring, are associated with specific points on the potential quasi-energy curve, the survival period coinciding with the "potential well" and the reproductive period with the "potential barrier".

If one considers a particular value of the body mass, such that a minimal change of mass will move the organism to a "well" or "barrier" on the quasi-energy curve, this may be regarded as the energetically optimal body mass, that is to say, the point of inflexion between m_1 and m_2 may be regarded as an energetically optimal size m_{opt} in the range $[m_{min}, m_{max}]$ for this organism.

Because Fig. 2 is a semi-logarithmic plot, it is clear that optimum size is at approximately the centre of the size range, that is,

$$\log m_{opt} \approx \frac{1}{2}(\log m_{min} + \log m_{max})$$

or, on a linear scale, the optimal size will be the geometric mean, that is,

$$m_{opt} \approx \sqrt{m_{min} \cdot m_{max}} \quad (4)$$

In this case the optimum size is biased towards a low value because the geometric mean is less than the arithmetic. This result also has real biological meaning in so far as the size distribution of individuals in a population and of species in a genus is normal on a semi-logarithmic scale⁶ (Fig. 3) and its maximum coincides with the energetically optimal size.

There are organisms with the same exponent b and the same size range $[m_{min}, m_{max}]$, but with different coefficients a in equation (1), for example, large poikilothermic and homeothermic organisms². The homeothermic animals are generally regarded as having reached the highest

energy level. The concept of quasi-energy makes the definition of the energy level of the organism precise because its curve approaches the reference level H_0 (Fig. 2) and adopts the same values on the boundaries

$$H(m_{min}) \approx H(m_{max}) \approx H_0 \quad (5)$$

Thus we may call H_0 a quasi-energy level of the organism and a step in organic evolution, from the point of view of bioenergetics, would be the achievement of a new quasi-energy level^{2,3}.

Table 1. VARIATION OF MEAN VALUES (M) AND COEFFICIENT (CV) OF THE BODY MASS (g) IN COMMON AND PYGMY SHREWS IN THE KIEV AREA THROUGHOUT LIFE

Months	M	CV	\pm	Scv	No.	M	CV	\pm	Scv	No.

VII	11.8	10.9	\pm	2.22	12					
IX	11.8	10.7	\pm	2.38	10					

$CV = 100 \times \sigma/\bar{x}$; $Scv = CV/\sqrt{2n}$.

Other properties of organisms (such as variability and structural energy) are related to the quasi-energy (Table 1 and Fig. 4). Variability proves to be in direct proportion to the quasi-energy level while the structural energy is, on the contrary, in counterbalance with it.

The problem of the relationship between the functions Q and q can alternatively be approached by considering their intersection. Both functions possess the same range of definition $[m_{min}, m_{max}]$, but have different ranges of significance $[Q_{min}, Q_{max}] \neq [q_{min}, q_{max}]$ and dimensions

Fig. 2. Potential quasi-energy $H(m)$ in shrews.

Fig. 3. Dispersion of species in the genus *Sorex*.

Fig. 4. Structural energy G and quasi-energy H dynamics in *Orchestia bottae* (Amphipoda, Tellioidae)*.

$$[Q] = \frac{\text{kcalories}}{\text{hour}} \neq [q] = \frac{\text{kcalories}}{\text{kg} \cdot \text{h}}$$

If we now introduce a new function $P(m)$, with the same ranges of definition, significance and dimension as the total heat production $Q(m)$, and simultaneously closely related to the specific heat production $q(m)$ according to the linear equation, then

$$P(m) = \alpha q(m) + \beta$$

In this case the linear transformation parameters α and β enable $P(m)$ to meet the conditions of having the same range as $Q(m)$

$$\begin{aligned} P(m_{\min}) &= Q(m_{\max}) \\ P(m_{\max}) &= Q(m_{\min}) \end{aligned}$$

Thus the new function is

$$P(m) = -\frac{\Delta Q}{\Delta q} q(m) + \frac{\Delta H}{\Delta q}$$

where ΔQ , Δq , ΔH represent increments of Q , q , H within the range $[m_{\min}, m_{\max}]$. There is a coincidence point m_0 which can be found from the equation $P(m) = Q(m)$, or

$$-\frac{\Delta Q}{\Delta q} q(m) + \frac{\Delta H}{\Delta q} = Q(m)$$

Using equation (3), this equation can be rewritten in a symmetric form

$$\frac{\Delta Q}{Q(m)} + \frac{\Delta q}{q(m)} = \frac{\Delta H}{H(m)}$$

In our case $\Delta H \approx 0$ (5), so that

$$m_0 \approx -\frac{\Delta Q}{\Delta q} \quad (6)$$

Expressing Q and q in terms of $H(m)$ by means of equations (2) and (3)

$$Q(m) = \sqrt{mH(m)} \text{ and } q(m) = \sqrt{\frac{H(m)}{m}}$$

and using equation (5) anew, we get from equation (6) the point of intersection as

$$m_0 \approx \sqrt{m_{\min} \cdot m_{\max}}$$

which thus coincides with energetically optimal size

$$m_0 \approx m_{\text{opt}}$$

Thus the intersection method gives the same result as a multiplicative one, although at first sight they have nothing in common.

Measuring the Change of Population Fitness by Natural Selection

Haldane and Van Valen^{1,2} measured the intensity of natural selection by the difference of the mean fitness from the optimum. Haldane used the formula $I_H = \log_e w_0 - \log_e \bar{w}$ where w_0 is the fitness of the optimum phenotype and \bar{w} is the mean fitness. Van Valen's formula is $I_V = (w_0 - \bar{w})/w_0$ which gives values similar to Haldane's. But w_0 may be unknown. The optimum phenotype with the highest fitness may not have occurred in the population. If, for example, among existing phenotypes fitness increased as a linear function of a character, there would be no way of obtaining a value of the optimum phenotype. Values of I_H and I_V would then be arbitrary and depend on an arbitrary value chosen for w_0 .

The intensity of selection is a measure of how far selection has to go to reach whatever optimum—theoretical or actual—happens to be chosen. It is surely of more interest to know what change of fitness occurs during the period within the life-cycle of the organism when the selection is actually taking place. Let w be the fitness of a phenotype and let the character being measured have a phenotypic value of x . Let x occur with probability P . Then by definition the mean fitness is

$$\bar{w} = \sum Pw$$

After selection x has the probability

$$P' = Pw/\bar{w}$$

Therefore the mean fitness after selection is

$$\begin{aligned} \bar{w}' &= \sum P'w = [\sum Pw^2]/\bar{w} \\ &= (V_w + \bar{w}^2)/\bar{w} \end{aligned}$$

where V_w is the variance in fitness. Thus

$$\bar{w}' - \bar{w} = \Delta \bar{w} = V_w/\bar{w}$$

This is, of course, Fisher's fundamental theorem of natural selection³. Because it is applied here only to the selection acting on phenotypes it is exact and general.

I used a model of selection for the optimum of a quantitative character to derive formulae for the changes in the mean and variance of x (ref. 4). The intensity of the selection on x can then be calculated. In this model the fitness is given by

$$w = 1 - \alpha - K(\theta - x)^2$$

where θ is the optimum value of x . When $x = \theta$, w is at its optimum value of $1 - \alpha$. This seems to be the most general model of selection that can be solved for $\Delta \bar{w}$ for any distribution of x . Similar solutions can be derived for other models of w if x is normally distributed. In general, however, x must be assumed to have any frequency distribution with a mean of x and second, third and fourth moments about the mean of V_x , μ_{3x} and μ_{4x} . It is easy to show that if

$$w = 1 - \alpha - K(\theta - x)^2$$

then

$$\begin{aligned} \bar{w}' &= 1 - \alpha - K(\theta - \bar{x})^2 - K V_x \\ V_w &= K^2 \{ \mu_{4x} - V_x^2 + 4 V_x(\theta - \bar{x})^2 - 4 \mu_{3x}(\theta - \bar{x}) \} \end{aligned}$$

and

$$\Delta\bar{w} = V_w/\bar{w}$$

in agreement with Fisher's fundamental theorem.

It can be proved⁴ that

$$\Delta\bar{x} = \frac{2KV_x(\theta - \bar{x}) - K\mu_{4x}}{1 - \alpha - K(\theta - \bar{x})^2 - KV_x}$$

$$(\Delta\bar{x})^2 + \Delta V_x = \frac{KV_x^2 - K\mu_{4x} + 2K\mu_{3x}(\theta - \bar{x})}{1 - \alpha - K(\theta - \bar{x})^2 - KV_x}$$

and from these equations

$$\theta - \bar{x} = \frac{V_x^2(\Delta\bar{x}) - \mu_{4x}(\Delta\bar{x}) + \mu_{3x}[(\Delta\bar{x})^2 + \Delta V_x]}{2V_x[(\Delta\bar{x})^2 + \Delta V_x] - 2\mu_{3x}(\Delta\bar{x})}$$

$$\varphi = \frac{1 - \alpha}{K} = \frac{2V_x(\theta - \bar{x}) - \mu_{3x}}{\Delta\bar{x}} + (\theta - \bar{x})^2 + V_x$$

Normally we only want to know the relative fitnesses of the phenotypes. If we put $\alpha = 0$, the phenotype $x = \theta$ is given a relative fitness of one. Thus $K = 1/\varphi$ and the "fitness function" is

$$w = 1 - (\theta - x)^2/\varphi$$

from which the relative fitness of each phenotype can be calculated. If the absolute mean fitness is known—for example, if the total proportion of survivors during the period of selection is known—then it is a simple matter to calculate α and thus obtain the absolute fitness function.

When the values of $\theta - \bar{x}$ and φ have been calculated, the change in relative fitness can quickly be found. Because $\Delta\bar{w}$ is the change in mean fitness $\Delta\bar{w}/\bar{w}$ is the relative change in mean fitness which is $\Delta\bar{w}/\bar{w} = V_w/\bar{w}^2$. Thus

$$\begin{aligned} \Delta\bar{w}/\bar{w} &= \frac{K^2[\mu_{4x} - V_x^2 + 4V_x(\theta - \bar{x})^2 - 4\mu_{3x}(\theta - \bar{x})]}{[1 - \alpha - K(\theta - \bar{x})^2 - KV_x]^2} \\ &= \frac{\mu_{4x} - V_x^2 + 4V_x(\theta - \bar{x})^2 - 4\mu_{3x}(\theta - \bar{x})}{[\varphi - (\theta - \bar{x})^2 - V_x]^2} \end{aligned}$$

As an example, the change of relative fitness can be calculated for the selection acting on the spotting of *Maniola jurtina*. Dowdeswell's⁵ data of samples of the butterfly before and after selection of the newly emerged adults are given in Table 1.

Table 1. *Maniola jurtina* BEFORE AND AFTER SELECTION

No. of spots	No. of the females	
	Before selection	After selection
0	124	294
1	67	111
2	34	53
3	10	13
4	2	0
Total	237	471

We find $\bar{x} = 0.72996$; $V_x = 0.84202$; $\mu_{3x} = 0.89592$; $\mu_{4x} = 2.65987$; $\Delta\bar{x} = -0.18643$; $\Delta V_x = -0.26573$, giving $\theta - \bar{x} = -2.85546$ and $\varphi = 39.5943$.

By the model, the optimum fitness occurs at the point $x = -2.1255$, an impossible phenotype on the scale of measurement of the character. This is not necessarily unreasonable, however. It is almost certain the selection is acting on some underlying physiological character of which spot number is but a partial manifestation. The optimum of the physiological character presumably corresponds to a spot number of -2.155 which cannot, however, be observed phenotypically in spots. Applying the formula for the change of relative fitness, we get

$$\begin{aligned} \Delta\bar{w}/\bar{w} &= V_w/\bar{w}^2 \\ &= 0.0423 \end{aligned}$$

The fitness has therefore increased by 4.23 per cent by natural selection. If fitness is a linear function of the character, then it is easy to show that $\Delta\bar{w}/\bar{w} = (\Delta\bar{x})^2/V_x$. For the data on *Maniola* this formula gives $\Delta\bar{w}/\bar{w} = 0.0413$, which is in fair agreement with the previous value. This is because the values of x are a long way from their optimum and fitness is increasing more or less linearly.

If x has a normal distribution and the mean is at the optimum so that $\bar{x} = \theta$ and $\mu_{3x} = 0$, then $\Delta\bar{x} = 0$ and

$$\varphi = \frac{V_x(3V_x - V_{x'})}{V_x - V_{x'}}$$

where $V_{x'}$ is the variance after selection. This gives

$$\begin{aligned} \Delta\bar{w}/\bar{w} &= \frac{(V_x - V_{x'})^2}{2V_x^2} \\ &= \frac{1}{2}(1 - V_{x'}/V_x)^2 \end{aligned}$$

For example, Van Valen and Weiss⁶ obtained data showing that between young and old rats the variance in measurements of their teeth was reduced by a proportion $V_{x'}/V_x = 0.188$. Thus fitness increased by 0.0177 or 1.77 per cent. The corresponding formula for the intensity of selection is $I = (V_x - V_{x'})/(3V_x - V_{x'})$ which gives $I = 0.0859$ (ref. 4). Thus fitness would be increased by a proportion $I/(1 - I)$ or 9.40 per cent if all individuals had the optimum size of tooth. But this is an increase in fitness that can never be achieved, for there will always be some variation, environmental and genetic, round the mean. In general, therefore, the increase of relative fitness, $\Delta\bar{w}/\bar{w}$, is a more satisfactory measure, because it gives as a percentage the increase of fitness that has actually occurred.

Table 2. RELATIVE FITNESSES OF PHENOTYPES BEFORE AND AFTER SELECTION

Phenotypic values	Frequencies		Relative fitness	Relative fitness of <i>Maniola</i>
	Before selection	After selection		
x	f	f'	w	w
0	f_0	f'_0	1	1
1	f_1	f'_1	$f'_1 f_0 / f_1 f'_0$	0.69875
2	f_2	f'_2	$f'_2 f_0 f_1 / f_2 f'_0 f'_1$	0.65746
3	f_3	f'_3	$f'_3 f_0 f_1 f_2 / f_3 f'_0 f'_1 f'_2$	0.54830
4	f_4	f'_4	$f'_4 f_0 f_1 f_2 f_3 / f_4 f'_0 f'_1 f'_2 f'_3$	0

Provided there are sufficient numbers in the samples of individuals before and after selection, the relative fitnesses of the phenotypes can be calculated empirically without using any particular model of selection. If the character is a continuous variate it will be necessary to divide its range into suitable class intervals and to calculate the relative fitnesses of the phenotypes in each class interval. They are calculated as in Table 2. These relative fitnesses will, of course, be subject to large sampling errors, for in the sample of *Maniola* the numbers of individuals with three and four spots are very small. The data on *Maniola* give $\bar{w} = 0.8382$ and $V_w = 0.03350$, so that $\Delta\bar{w}/\bar{w} = 0.04768$, which is slightly higher than the value obtained from the model of selection for an optimum. But the values agree within the usual limits of error.

SOPHIST'S DELIGHT

Fallacies

By C. L. Hamblin. Pp. 326. (Methuen: London, March 1970.) 55s.

ONE cat has one more tail than no cat. No cat has two tails. Therefore all cats have three tails. This fallacy was put to me by, and indeed explained by, the deputy commander-in-chief at Bomber Command during one of the crises of the Second World War. I now offer it in gratitude to Professor Hamblin; for I find from his book that it belongs to Aristotle's class of "fallacies of equivocation".

Professor Hamblin notes that "There is hardly a subject that dies harder or has changed so little over the years". The weakness of the human mind for fallacy is indeed hardly less eternal than its search after truth; and to ponder such timeless matters is a refreshment for the man of science who knows that most of his work will be superseded within a few years. For in contemplating fallacy he will find himself in company with some of the keenest minds of the past, starting with Aristotle, who discerned thirteen kinds of fallacy, six of them dependent, as is the three-tailed cat, on the misuse of language, and the others on different modes of confusion of thought. Aristotle even described how such confusion may be deliberately effected: to argue at great length so that one's opponent loses the thread, or at such speed that he cannot follow, or to make him angry so that he cannot think clearly. While Hamblin recognizes Stephen Potter as a modern parallel, he might very properly have also mentioned F. M. Cornford, whose *Microcosmographia Academica* vividly bears the Aristotelian stamp on its chapters on argument and on the conduct of business.

Aristotle's list has been augmented through the centuries, especially during the disputations of the schoolmen, who developed much skill in the induction of fallacies by confusion of argument. The "*argumentum ad hominem*" is an example; by its aid, home rule for Ireland could be condemned because its great advocate, Parnell, was an adulterer. And the scope of the exercise is indicated by the further twenty-two "argumenta" on Hamblin's list before he comes to his own "*argumentum ad nauseam*". Once again, to offer a crumb that may have escaped Aristotle (unless with a prescient sense of pun he included it under solecism), I may mention that a scientist in government circles is reputed to have originated an even more devastating device for demolishing his adversary than any in Aristotle's armoury. It was, I think, at a meeting of the deputy chiefs of staff. The scientist had taken the precaution of discovering his adversary's arguments in advance, and he recognized that they were logically superior to his own. His counter was simply to arrive at the meeting early, and to take each deputy chief aside confidentially and tell him what the adversary would say with the implication that this contained a subtle fallacy that would nevertheless, of course, be as obvious to the deputy chiefs as it was to him. The unfortunate adversary therefore presented an excellent case and was bewildered to have it rejected without the scientist having to say a word, simply because each deputy chief had been flattered into pretending that he was clever enough to see the fallacy.

Francis Bacon gave much attention to fallacies in *The*

Advancement of Learning, where he described them as "idols", and Hamblin remarks that Bacon's work was a turning point in their treatment, so that "from now on, some part of the analysis of fallacy will involve an appeal to psychological factors, as in the idols of the tribe and cave, or to social ones, as in the idols of the market place". And, following Bacon's condemnation of the academics who "have tumbled up and down in their own conceits", the Royal Society took as its motto "*Nullius in Verba*". But even the society was not immune to the shrewd attack of Charles II with his famous question about the displacement of water by a live fish in a bowl. This falls into Aristotle's class of "fallacies of many questions" in which the fallacy is presupposed in the question asked; and protagonists of multiple-choice questions would do well to take heed, as Banesh Hoffmann has pointed out in *The Tyranny of Testing*.

Hamblin's account of the Royal Society's floundering over the fish might have benefited from a scientific collaborator who could have resolved for him the question that he poses regarding the weight of a closed cage containing a bird in flight: and this collaboration might have resulted in more discussion of those more interesting fallacies that arise not from any sleight-of-mind, but from the errors that sometimes inevitably arise in the application of scientific method. False correlation is one frequent source, illustrated by Musselwhite's observations that nature had arranged for black men to live in hot climates, and his deduction that Europeans should therefore wear dark suits in the tropics. Such correlations are bound to be made from time to time as science attempts to advance: no scientist, for example, in Western Europe in the 17th century could be blamed for stating that all swans were white. It was a good working conclusion until the discovery of Australia.

The dangers of inductive fallacy are exemplified in the history of vacuum, even beyond the point to which Professor Hamblin takes it. Arnauld in the *Port Royal Logic* (1662) cited the fact that suction pumps could not raise water by more than about 32 feet as evidence against a fallacious conclusion from the ancient observation that nature abhorred a vacuum. But, ironically, Arnauld's own conclusions turn out to be somewhat fallacious, for, even as Hamblin was writing, the National Engineering Laboratory was showing that with due precautions water can be pumped by suction to 56 feet (*New Scientist*, January 29, 1970).

Again, arguments that are qualitatively valid at all scales of physical dimensions may give correct conclusions at one scale but misleading ones when the scale is changed. Brougham supposed, for example, that natives carry burdens on their heads because they had subconsciously discovered that these burdens then weigh less because they are further away from the centre of the Earth (*Nature*, 46, 53; 1892). His argument was qualitatively correct, but the effect is so trivial that it has nothing to do with the action. Again, it may be valid to argue that more light will come out of a gas discharge tube if more gas is present; this is true at low pressures, but not at high ones, where self-reversal may set in. And it may not be a false analogy (a type of fallacy first discussed by Abraham Fraunce in 1588) to suggest that the same may be true of an educational system.

I would have welcomed more attention to Occam's razor. Hamblin does, indeed, mention it; and he tentatively uses it to deal with belief in ghosts, as I myself have used it for flying saucers. But a further discussion of its powers and defects would have been well worth a place. Inevitably, it sometimes leads to error, when it is made to operate on selected evidence, but it is the best tool that we have.

Mathematics is not treated at all in the book; but it would have been interesting to see an analysis of mathematical fallacies, going beyond Canning's dictum that "nothing was so fallacious as facts, except figures". How

many schoolboys, on learning that $e^{2\pi i} = 1$, have boggled at the consequences of taking logarithms?

Hamblin excurses into Indian logic, where fallacies have also had much attention, notably in the *Nyaya Sutra*. This is often printed with a commentary by the author of the *Kama Sutra*, Vatsyayana, who therefore seems to be "from the productions which he left behind him" the oriental equivalent to the younger Gordian (*Nature*, 205, 949; 1965).

This glance at India completes the first half of the book, which is historical and, as the blurb says, is little less than a history of logic itself. In the second half, Hamblin, whose interest in the matter started with Buridan, aims at showing logicians the scope and limitations of logical reasoning; and although the book is not directed primarily to natural science, the man of science may gratefully contemplate its lessons.

R. V. JONES

IMPROBABILITIES

The Implications of Induction

By L. J. Cohen. Pp. vii + 248. (Methuen: London, April 1970.) 75s.

SINCE Francis Bacon, students of inductive logic have generally recognized two types of inductive inference: from numbers and from variety of instances, or induction by simple enumeration and induction by elimination of rival hypotheses. Induction by simple enumeration can be regarded as a special case of inference to population hypotheses from samples, and it has therefore often been assimilated to probabilistic inference, particularly in the confirmation theories of Keynes, Jeffreys, Reichenbach and Carnap. It has, however, been found surprisingly difficult to incorporate into such probabilistic theories the requirement of variety of irrelevant circumstances of observation, which is certainly present in all scientific testing of general hypotheses. Mr Cohen argues that this difficulty is not accidental or surmountable in principle; it is the consequence of a radical distinction between the two traditional methods of induction, which he thinks cannot in principle be assimilated to each other, and which have different logics. His book consists of an argument for, and formal development of, a logic of inductive support, which he claims is appropriate for induction by elimination and is not expressible in terms of any functions of probabilities.

Understood as an explication of eliminative induction many of the *prima facie* puzzling features of this logic become plausible. For example, an immediate and apparently highly counter-intuitive consequence of Cohen's axioms is his so-called "instantial conjunction principle". This states that if any evidence *E* supports a singular substitution instance ("a is a raven only if black") of a universal generalization ("all ravens are black"), then to just the same extent *E* supports the conjunction of any number of such substitution instances ("a and b and . . . are ravens only if black"). That is to say, if observation of a single black raven *a* is support for the assertion of the casual or essential tie which seems to be implied by "a is a raven only if black", then it is equal support for this causal tie in any instance of ravenness. From the point of view of testing of a statistical hypothesis this is absurd, but if the assertion of a cause can somehow be validated by the elimination of all variables other than ravenness which might have been relevant to blackness, it becomes intelligible. To the standard objection to eliminative induction of this kind, that we can never know what the complete list of all such other variables is, Cohen's reply seems to be that its determination is a matter for scientists to judge. What constitutes a "cause" for science is prior to inductive investigation. That this is his view seems to be confirmed by his rather cavalier dismissal of those cruces for a satisfactory theory of

induction: Hempel's and Goodman's paradoxes. Both types of paradox, he argues, depend on misunderstanding the semantics of test-statements for causal laws. But what non-inductive criteria there are for the causal character of laws he does not tell us. This question is so crucial to the inductive theory presented here that absence of any discussion of it makes the theory at best an incomplete contribution to the philosophy of induction.

MARY HESSE

HARTLIB AND HIS CIRCLE

Samuel Hartlib and the Advancement of Learning

Edited by Charles Webster. (Cambridge Texts and Studies in the History of Education.) Pp. x + 220. (Cambridge University Press: London, February 1970.) 40s.

Mathematical and Philosophical Works

By John Wilkins. (Two volumes in one.). (Cass Library of Science Classics, No. 11.) Pp. xiv + 261 + xvi + 265. (Cass: London, February 1970. First published 1708.) 147s.

WHEN Robert Boyle returned from his private education in Geneva to an England in the throes of civil war in 1644, his youthful idealism soon swept him into the orbit of a remarkable Prussian refugee from the Thirty Years' War, Samuel Hartlib. Hartlib was influenced partly by Francis Bacon's vision of a new kind of science that would establish man's dominion over nature; but even more so, by continental reformers like Alstead, Andreae, and Comenius, whose "new science" was at once more mystical and more starkly utilitarian than Bacon's, and was part of a greater social, religious, and educational reform which they believed would be a preparation for the millennium. Boyle's celebrated reference to an "Invisible College" seems to refer to Hartlib and his associates. The calling of the Long Parliament in 1640, and later the victory over the Royalists, signalled for them the imminent realization of the Biblical "New Eden" in England. Hartlib and his group bombarded Parliament with a remarkable range of plans for reorganizing school and university education, agriculture, arts and crafts, and employment and social security.

But with Parliamentary victory came disunity among the reformers, and a dampened enthusiasm for change on the part of the new rulers. Two years before the Restoration, Hartlib wrote to Boyle that he was "wonderous glad that you have written of the present Protector's intentions for contentancing and advancing of universal useful learning in due time"; but he now despaired of realizing his dream, except perhaps in Virginia. Neglected by acquaintances who once found him useful as a "universal intelligencer", and who were now banding together in the new Royal Society, he died in poverty in 1662.

In a long introduction to his selection of Hartlib's papers on the "advancement of learning", Mr Charles Webster has provided an important reassessment of the activities of Hartlib and his associates. His account includes many new details from the unpublished Hartlib Papers, and his reappraisal of Hartlib's influence on the early Royal Society is of particular interest for the history of 17th century English science.

As Webster points out, Boyle always retained something of the religious outlook formed in the Hartlib circle. But he soon moved away from its mystical-chemical and extreme-utilitarian idea of science towards that mechanical and "corpuscular philosophy" which he was to be so influential in propagating. Boyle's taking up lodgings in Oxford about 1651 clearly marked the break. He came at the invitation of John Wilkins, "intruded" Warden of Wadham College, who asked him to join the youthful, scientific group which flourished at Oxford since the late 1640s.

Wilkins showed little appreciation of the revolutionary conceptual innovations of Galileo and Descartes which were the inspiration of the most gifted members of his group. Except for a distaste for mystical chemistry, his ideal of science resembled that of Hartlib's. He looked to it primarily for mechanical devices and inventions to advance trades and crafts. Nevertheless, he was an important representative of the gentleman-amateur tradition of 17th century English science, and the new and reasonably priced republication of his works illustrates his role in popularizing and defending the Copernican system, and the astronomical discoveries of Tycho, Kepler, and Galileo. In 1638, he foresaw the time when man would make a passage to "the World in the Moon":

"Yea, but (you will say) . . . we have not now any Drake, or Columbus, to undertake this voyage, or any Daedalus to invent a conveyance through the air.

"I answer, though we have not, yet why may not succeeding times raise up some spirits as eminent for new attempts, and strange inventions, as any that were before them?"

P. M. RATTANSI

SPACE PHYSICS

Cosmic Ray Physics

Nuclear and Astrophysical Aspects. By Satio Hayakawa. (Interscience Monographs and Texts in Physics and Astronomy, Vol. 22.) Pp. xi + 774. (Wiley (Interscience): New York and London, February 1970.) 370s.

THE subject matter of the series of biennial conferences on cosmic ray physics organized by the Cosmic Ray Commission of IUPAP has in the past shown very clearly the changing interests in the field over the years. Before 1953, fundamental particles and high energy collisions were the dominant topics for discussion whereas, from 1953 onwards, the emphasis has been very much on the geophysical, heliophysical and astrophysical aspects of cosmic rays. This change has been partly the result of the appearance on the scene of high energy laboratory accelerators and partly because of the advent of satellites and space probes which permit cosmic ray observations outside the magnetosphere and have led to an enormous increase in our understanding of the field and particle environment in space.

About a half of Professor Hayakawa's book is devoted to the physics of high energy collisions, including fundamental particles and electromagnetic interactions, and in this part there is collected together a great deal of useful and readily accessible information in the form of graphs and formulae. The subject of high energy interactions is still in the developing phase and the author presents a convenient account of both the relevant experimental data and of current theories. This is followed by chapters on the cosmic ray beam in the atmosphere and underground and on large cosmic ray air showers. Finally, there is a long section, almost 200 pages, dealing with the astrophysical aspects of cosmic rays and the problems of the cosmic acceleration process and the origin of the particles.

It is hardly surprising that in a book of this length there are some obscurities, errors and inaccuracies. For example, on p. 11, there is no clear distinction between history and current understanding, with the result that the reader is left with the impression that Forbush decreases are caused by the ring current—a suggestion made in 1937 and discarded as incorrect quite soon afterwards; on p. 159 elementary particles are categorized as belonging to the familiar four groups of photon, lepton, meson and baryon, but unfortunately in the accompanying table (pp. 160–161), which lists the particles, the term baryon nowhere appears and pions appear under the heading leptons; on p. 532, the trapping of energetic

particles in the solar system is discussed in a semi-quantitative way, but without any reference to the convective effects of the solar wind which, in fact, dominates the situation. There is often a marked absence of discussion of the physical ideas underlying the mathematical formulae, which number well over a thousand, and some parts of the book, which was completed in the autumn of 1966, read very much like lecture notes. Indeed, the author points out in the preface that some sections are based on courses of lectures he has given. It is by no means the most readable book that has been produced on cosmic ray physics and is certainly to be recommended for use as a reference book rather than as light reading. H. ELLIOT

BORN'S VIEW OF PHYSICS

Physics in My Generation

By Max Born. (Heidelberg Science Library.) Pp. vii + 172. (Longman: London and New York, April 1970.) 50s.

"THE idea of collecting these essays occurred to me when, in the leisure of retirement, I scanned some of my own books and found that two of the more widely read showed a startling change of attitude to some of the fundamental concepts of science", writes the author in the preface. The essays are mostly reprints of articles or records of lectures given on various occasions; they may have been addressed to laymen in science or to Nobel Laureates.

As a frame to the book, Born has chosen the "Introduction to Einstein's Theory of Relativity" (1921) and the "Postscript to the Restless Universe" (a young person's book on elementary atomic and nuclear physics dedicated to his son Gustaf, 1951), from the two books referred to earlier.

The first, the principal part of the book, gives much insight into the development of physical concepts in the fifty years from 1901 onwards. Born has himself been an active participant in formulating quantum mechanics and, though he did not himself take part in working in general relativity, his friendship with Einstein was originally based on Einstein feeling "completely understood and appreciated", and this led to a lifelong discussion on basic issues. The dramatic evolution in scientific thought comes out well in these essays; they are therefore enjoyable and valuable not only for scientists but also for those interested in the history of the materialistic world picture. Most of the essays in this section have previously been published under the same title by the Pergamon Press in 1956.

The second part contains four essays of a different slant, Born's concern with the problems of nuclear energy. A man of great sensitivity and wide interests, he was plunged into deep depression and despair over the possibility that the applications of modern science might lead to the extermination of mankind. Thus not only the laws in physics had changed from deterministic ones to statistical ones, but the proud attainments of the natural sciences had become of doubtful value.

EGON BRETSCHER

HAMILTON'S THEORY

An Introduction to Hamiltonian Optics

By H. A. Buchdahl. (Cambridge Monographs on Physics.) Pp. xv + 360. (Cambridge University Press: London, March 1970.) 120s; \$18.50.

THIS book contains the best account of Hamilton's theory that I have come across. Applications to electron optics as well as to ordinary optics are considered, and the author keeps to a pleasant lecturing style of writing, although the nature of the subject matter (which is often heavily algebraical) makes this difficult at times.

There are twelve chapters, each with a problems section

at the end. Outline solutions to the problems are given at the end of the book. Printing and diagrams are excellent.

Chapter one, a short one, deals in an introductory way with Fermat's principle. The second chapter introduces Hamilton's point characteristic V and the general notion of a characteristic function, then the angle characteristic T , the "mixed" characteristics W_1 and W_2 , and finally the notion of an aberration function. Chapter three discusses the relation between symmetries of optical systems and invariance properties of characteristic functions. Ordinary centred systems, of course, provide the most important practical examples, but the discussion is more general. Chapters four and five develop the theory of the symmetric system (the ordinary "centred system") and chapter six that of systems with additional symmetries. Chapter seven discusses semi-symmetric systems, which have an axis of symmetry but no plane of symmetry containing the axis. Here the medium is necessarily anisotropic. (Electron microscopes using magnetic focusing provide an example of this type of system.) Systems with other types of symmetry are discussed more briefly in the following two chapters. In chapter ten, a fairly short discussion of chromatic defects of the image is given. Chapter eleven deals with the effects of anisotropy, such as can occur in crystalline media.

The last chapter, on the computation of aberration coefficients, begins with an interesting discussion on whether the Hamiltonian or the Lagrangian method of computation should be considered the best practical basis for optical (and dynamical) computations. So far as optical computations are concerned, the author is probably better qualified than most experts to pass judgment on this question. He says: "The great simplicity of the Lagrangian method leads me to believe that it, rather than the Hamiltonian method, is best adapted to the problem of practical calculations; though this is admittedly a mere expression of opinion". Nevertheless, because of the interest of this question and also to round off the treatment, he goes on to give one possible procedure of calculating characteristic functions, that is to say the coefficients of their power series.

The book is an outstanding contribution to the "classical" literature of the subject and deserves a place in every optics library.

E. H. LINFOOT

ABELIAN GROUPS

Infinite Abelian Groups

By Laszlo Fuchs. Vol. 1. (Pure and Applied Mathematics, Vol. 36.) Pp. xi + 290. (Academic Press: New York and London, January 1970.) 140s.

THE rate at which group theory is growing is indicated by the fact that the author, intending to prepare a revised edition of his 1958 book on Abelian groups, found that in order to take reasonable account of work done during the past decade a completely new book must be written. His new volume should therefore be particularly useful to the young postgraduate student, for in many places it brings him up to the frontiers of present-day knowledge, shows him modern methods and, in addition, offers a number of explicit research problems to challenge him. The reader should have some knowledge of abstract algebra, set theory, and topology; from this point onwards the book is self-contained, but a previous acquaintance with the fundamental properties of Abelian groups and with the type of austere abstract reasoning involved, while not absolutely essential, is highly desirable. The author has striven for clarity of expression, and has not thought the provision of numerous exercises for the reader beneath the dignity of a volume intended for postgraduate study; these are genuine exercises, not

sections of theory for which no room could be found in the main text.

The influence of homological algebra is evident; the 1956 book on this topic by Cartan and Eilenberg unified cohomology theory for groups and classes of algebras and helped to clarify and simplify certain aspects of group theory. The concepts of categories and functors supply generality, and the diagrammatic representation of homomorphisms gives an intuitive grasp of complex relationships.

The first volume deals chiefly with important classes of Abelian groups, direct sums, divisible groups, and the like, and extension problems and torsion products. The second volume is to deal with structure theory and applications.

T. A. A. BROADBENT

HYDRATION PROCESSES

Hydration and Intermolecular Interaction

Infrared Investigation with Polyelectrolyte Membranes. By Georg Zundel. Pp. xi + 310. (Academic Press: New York and London, January 1970.) 168s.

THIS volume summarizes the results of investigations by infrared spectroscopy carried out at the University of Munich on the molecular processes involved in hydration, particularly of polyelectrolytes in the form of cation-exchange resins.

The assignment of the absorption bands of polystyrene, polystyrenylsulphonyl chloride and of polystyrene-sulphonic, -selenic, -phosphinic and -thiophosphonic acids and their salts is fundamental to the interpretation of the measurements, and is therefore analysed critically. A careful examination is also made of the effect of hydrogen-bonding on the spectra of water and deuterated water, as well as of such phenomena as the effects of the location of the cation with respect to the oxygen atoms of the anion and of the degree of hydration on the stretching vibrational frequencies of polyelectrolyte anions. The effects of hydration and of association of acid groups on the spectra of the acids are collected and discussed. It is concluded that the two bands always occurring, which must be ascribed to OH or OD groups in the hydrogen-bridges connecting the acid groups, cannot be caused by a double minimum in the potential energy curve, but arise from a stretching vibration and an overtone of the bending vibration of the OH and OD groups. The natures of the various forms of hydrated proton which occur in these systems and the tunnelling effects in proton migration are discussed. Finally, the book gives details of the apparatus and techniques used in preparing cation-exchange membranes by production of a polystyrene membrane of definite thickness and degree of cross-linking and subsequent introduction of the desired acidic groups. The techniques used in the investigation of such membranes by infrared spectroscopy are also discussed.

The book provides an extremely important summary of the subject for those interested in the structures of these systems, but its price will seem high to British readers.

J. W. SMITH

CHEMICAL MARINE BIOLOGY

The Chemical Biology of Fishes

With a Key to the Chemical Literature. By R. Malcolm Love. Pp. xv + 547. (Academic Press: London and New York, January 1970.) 140s; \$21.

CHANGES in the external environment such as those of salinity, oxygen tension, temperature and pressure pose special problems to the maintenance of a state of homeostasis (constancy of internal environment) by fishes over the whole life cycle. This book provides a much needed survey and discussion on the chemical composition of tissues and body fluids of wild fish, as well as of fish that

have been at least partially acclimatized to the more standard conditions of life in an aquarium.

Chapter one is entitled "Towards a Valid Sampling Technique" and illustrates the problems encountered by research workers in obtaining animals in a sufficiently unstressed condition, from the sea or an aquarium, to determine what might be regarded as a normal range of concentration. This difficulty is apparent in almost all of the subsequent chapters when the author goes on to discuss the quantitative and qualitative changes in the chemical composition that occur during the life cycle, the effect of changes in the external environment and the effects of voluntary or involuntary starvation. Next, some differences between species are discussed and finally there are two appendices. The first appendix occupies 4 pages and consists of a simple, useful but somewhat uncritical index to references where individual chemical compounds have been detected in a wide variety of fishes. The second, of 16 pages, details the familial relationships of fish genera and gives the common and the systematic name as well as some qualitative indication of the chemical compounds that have been identified in the animal.

The aim of the book has been to relate a chemical and an analytical approach to the general biology of fishes. The selection of material for discussion has obviously been influenced to some extent by the author's own extensive research work and his own personal viewpoint. This is all to the good because the text is clearly and often entertainingly written in a highly individual style, but it should be noted that the features of metabolism that distinguish fish from other animals and the nature of fish enzymes have not been considered in detail.

To sum up, this monograph is an extensive reference work on the chemical composition of fishes up to 1968. It will be a valuable source of information to research workers and students who have interests in marine biology.

P. T. GRANT

THE ANIMAL WORLD

Animal Senses

By Robert Burton. Pp. 183+18 plates. (David and Charles: Newton Abbot, March 1970.) 65s.

THERE has always been a fascination in considering what the world must look, smell and sound like to animals. Is their world similar to ours, or is it a caricature of the detailed sensations which we feel? With the pace of electrophysiological investigations on sense organ function and the quantity of information coming from experiments on perception, there is almost a continuing need for reviews of this subject couched in terms which the layman understands. The author of this book has undoubtedly set out with this aim in mind, but in execution has come sadly wide of the mark. There are too many misleading statements and inaccuracies for the book to be recommended. One way in which the author errs is in the misapplication of terms which have quite specific meanings; thus, the explanation of kinesis on p. 19 is quite misleading, the performance of a worm in a T-maze is not a demonstration of a conditioned reflex, and a catalyst does not "supply energy".

In line with modern ideas the author describes experiments on sense organs but too often leaves out important details; for example, one electrode is insufficient to detect impulses in a nerve; where is the other one? With the anatomy and function of sense organs, mistakes again appear. Thus the hearing organs of grasshoppers (if we take the popular English usage of the word) are not in the legs, and the vibrations striking the antenna of a male mosquito are not transmitted down it but the whole flagellum is set into motion and it is the tuning of this flagellum which makes it so responsive to the wing note of the female. The illustrations are often over-simplified sketches of the true complexity of the sense organs;

glaring examples are the figures of the hearing organ of the grasshopper (which also shows the receptors in the wrong position) and of the facial pit of a viper.

One last strange feature of the book is the selection of entries in the bibliography; most of these are original papers which must be difficult for most of the potential readers to obtain. There are a number of short books which have been published within the past three years which would have been far more helpful for anybody looking for more information.

J. D. CATHY

DEFINING ECOLOGICAL CONCEPTS

Diversity and Stability in Ecological Systems

Report of Symposium held on May 26-28, 1969. (Brookhaven Symposia in Biology, No. 22.) Pp. vii+264. (Clearinghouse for Federal Scientific and Technical Information, NBS, US Department of Commerce: Springfield, Virginia.) \$3.0.

ONE of the pressing problems facing theoretical ecologists is the construction of a precisely defined framework on which to hang their data. Ecology is still dogged by vague, quasi-philosophical terms which lend themselves to a multitude of individual interpretations; two of such terms are diversity and stability. These concepts, together with their relationship to one another, form the theme of a symposium held at Brookhaven, New York, in May 1969. This volume is a valuable collection of nineteen papers from that symposium, given by a number of leading ecologists, and it serves to emphasize the need for unified models of ecological systems which will allow precise, mathematical formulation of our current embryonic concepts of ecosystem function.

Most of the authors interpret diversity in terms of the MacArthur model and take stability to mean the ability of a system to withstand and absorb major environmental perturbations. Contention arises in the definition of a major perturbation, and Lewontin helps to elucidate this by constructing a theoretical model in which there are several possible "basins of attraction" into which a system can settle; thus when perturbation becomes sufficiently violent the system may move to a new basin and achieve a new equilibrium. Margalef goes further and proposes a function which expresses stability in terms of biomass and attrition of that biomass.

Other papers, for example, those by Miller, Sanders and Slobodkin, are concerned with the origins of diversity, and all conclude that environmental stress leads to lowered diversity, whereas predictable environments (for example, the sea bed) allow a highly diverse, biologically accommodated biota to develop. Wilson provides experimental demonstration of this principle in his study of arthropod invasion of defaunated mangrove islands.

The time factor in the definition of stability is a familiar problem and Goulden shows long term increases in diversity by a study of fossil Cladocera in lake sediments, a subject further elaborated by Deevey.

A number of field situations are analysed in detail, for example, Watt's work on the behaviour of populations of insects and of epidemic diseases. He demonstrates an interesting, if enigmatic, correlation between upsets in population stability and volcanic eruptions. Cantlon concentrates on the effects of technology on natural populations of organisms, which provides a link with several papers dealing with the importance of stability and its accompanying (causative?) diversity to the survival of man on this planet. Some profitable thoughts emerge from these papers, though attempts to elevate ecology to a political system ("biocracy"—Caldwell) or even a religion ("not peace—but ecology"—Hardin) must be viewed with caution.

The volume is sensibly priced, poorly arranged and well worth reading.

PETER D. MOORE

PLANT CUTICLES

The Cuticles of Plants

By J. T. Martin and B. E. Juniper. Pp. vii + 347. (Arnold: London, March 1970.) 150s.

UNTIL recently there has been a relatively small literature available on the anatomy, chemistry and function of plant cuticles. By contrast there is a voluminous literature dealing with the holes that occur in cuticles because studies of the factors that affect the opening and closing of plant stomates have long been a favourite topic for investigation. With the development of the technique of gas chromatography, the availability of commercial electron microscopes, and the discovery of the procedures of freeze-etching and carbon replica formation, it is now possible to make intensive studies of the waxy cuticles of plants. This is currently an active research area and the authors of this book are to be congratulated on preparing a good book at the right time.

The combination of a chemist and a botanist has resulted in a wide cover of the literature because they have listed more than 1,000 references that impinge on their subject. For some, possibly too much emphasis has been placed on experimental methods, especially in the early chapters, but for others these chapters will be an invaluable source of references. There are few significant omissions; possibly the physics behind cuticular resistance to water vapour loss could have been better developed, and information on the actual magnitude of the resistance values could have been given in view of the great importance of the plant cuticle in controlling desiccation. Mention might also have been made of "chemical pruning agents" used in floriculture to kill selectively terminal meristems because these compounds almost certainly exert their effect due to the differences that exist between the cuticles of young and old tissues. A surprising inclusion is the interesting but relatively inaccessible work on the waxy cuticles of *Eucalyptus* sp. taken from an unpublished PhD thesis by Hallam.

I particularly like the introductory paragraph at the start of each chapter to help orientate the reader for what is to come. The cross-references within the text, the table of binomial and vernacular names and the glossary are also helpful. There is no tendency for the authors to simply tabulate a sequence of research findings as, throughout, current thinking has been summarized and presented as well-digested arguments.

I believe that the stated objectives of the authors in writing a book "of interest to all plant biologists and especially to workers in plant physiology, plant pathology, crop protection and to university, college and school teachers" although a rather large task has, in the main, been achieved. Finally, the publishers are to be commended for the high technical quality of the book; in particular, for the eye-catching dust cover, for the use of glossy paper throughout and, especially, for the high quality of the reproduction of electron micrographs, as carbon replicas of wax surfaces notoriously lack contrast. There is every chance that this book will become and will remain the standard reference on plant cuticles for quite some years to come and, as such, represents good value for money.

J. V. POSSINGHAM

HANGERS-ON

The Biology of Parasitic Flowering Plants

By Job Kuijt. Pp. 246. (University of California Press: Berkeley, Los Angeles and London, November 1969.) 143s.

PARASITIC flowering plants occupy a significant place in the flora of the world and in the agricultural economy of many tropical and sub-tropical regions, yet they form the one group that has been sadly neglected from the point of view of a unified presentation of the accumulated knowledge.

This book succeeds in filling this gap by surveying the whole field of parasitism by higher plants, from the lowly hemiparasite to the almost science fictional existence of *Rafflesia* and its relatives. Every aspect of the biology of these plants receives some attention.

An introductory chapter gives an absorbing account of the discovery of parasitism and the folklore, uses and medical and magical properties of parasitic plants. The author then allocates a chapter to each of the principal groups of parasitic flowering plants and makes a detailed examination of their important families and genera. The groups considered are the mistletoes; the sandalwoods; the broomrapes and figworts; the Rafflesiaceae, Hydnoraceae and Balanophoraceae—the families with relatively large parasitic complements; and *Cuscuta*, *Cassytha*, Lennoeaceae and Krameriaceae—isolated parasitic genera and families with few parasitic species. For each family the patterns of and variations in embryology, seed structure and germination, flower structure, fruit structure and dispersal, and the habit and mode of parasitism are described. These descriptions are illustrated by many excellent line drawings, mostly drawn by the author from material in the herbarium of the University of California, Berkeley. The half-tone illustrations, however, lack clarity on the matt paper, and many of them should merit special treatment in a book costing as much as this one.

Subsequent chapters deal with the structure of the haustorium, and the physiological and evolutionary aspects of parasitism. The foremost of these chapters describes the development and structure of the absorptive organs of the parasites, by which nutritional contact with the host is made. The author puts forward, in this chapter, a comparative account of haustorial structure. Absorptive organs are described, from the simple haustorium of the unspecialized root parasites, through the intricate haustoria of the specialized holoparasites, to the mycelium-like endophytic systems of the Rafflesiaceae. He concludes that, although the parasites display a marked degree of evolutionary plasticity in this respect, the haustorium of parasitic angiosperms represents a root in function and evolutionary origin. The physiological aspects of parasitism considered are germination and the exudation of germination stimulants by the roots of potential hosts, the nutrition and water economy of parasites, host ranges and the effects of parasites on their hosts. The final chapter discusses the possible evolutionary pathways of parasites and the relations between the structure of parasites and their evolutionary position.

The noticeable predominance of structure over function in this book is a reflexion not only of the author's research interests but also of our lack of knowledge in the fields of the physiological and nutritional aspects of parasitism and host relations.

The bibliography of some 700 references and the very detailed index combine to complete a book which is very readable and a long awaited reference book in this fascinating aspect of botany.

R. N. GOVIER

FOULING OF AN ESTUARY

Effects of Abatement of Domestic Sewage Pollution on the Benthos, Volumes of Zooplankton, and the Fouling Organisms of Biscayne Bay, Florida

By J. K. McNulty. (Studies in Tropical Oceanography, No. 9.) Pp. 107. (University of Miami Press: Florida, 1970.) n.p.

A STUDY of the ecological effects of pollution has to be comparative; unfortunately, by the time it becomes clear that such a study is needed, it is usually too late to observe the unpolluted condition. Dr McNulty has taken an unusual opportunity to make such a study in reverse.

The population of Miami increased from less than 2,000 to nearly 250,000 between 1900 and 1950, when 30 to 50 million gallons per day of its domestic sewage were being discharged into the Miami River or directly into the northern part of Biscayne Bay, which contains the port of Miami and separates it from Miami Beach. At the river mouth, coliform bacteria exceeded 100,000 per 100 ml. The impact of this pollution on the tourist industry eventually stimulated public demand for a treatment works. When plans were announced in the early 1950s, a series of surveys were made; the works began operating in 1956 and the surveys were repeated in 1960-61.

Benthic communities showed the greatest changes. At the periphery of a zone of organic pollution, such as existed in the mouth of the river, the food supply is abundant. Oxygen, which might otherwise have been limiting, was supplied by strong tidal currents, but most predators were excluded by conditions which were nevertheless abnormal. Dense populations of tolerant amphipods, polychaetes and lamellibranchs therefore developed. When the pollution was abated, diversity returned and the abundance of these tolerant forms was rapidly reduced. A marked reduction was also observed in the red algae typical of this community, but evidence from adjacent areas suggests that extensive dredging and perhaps hurricane damage may account for this. In the shallow and poorly flushed parts of the estuary, the concentration of inorganic phosphate and plankton volume both declined considerably, but elsewhere plankton showed little change between the two surveys. Changes in fouling organisms were generally unrelated to pollution, although there was a reduction in the numbers of tube-building amphipods. The unusual concentration of potential bottom food was not utilized by fish of commercial or sporting value, so the discharge had no fertilizing effect on the fisheries.

The volume is bound in thick boards and is well documented with tables and diagrams but, excluding these, there are only some 26 pages of actual text. The title pages, contents and prefatory material are well spaced and are not excluded from the pagination, so that the introduction (reviewing much of the previous work on estuarine pollution and eutrophication problems) begins on p. 19; a bibliography of 155 references extends over 15 pages. It might thus be considered an expensive item for a general library, but will prove useful to the specialist, particularly as little has yet been published about the effects of pollution in tropical waters.

A. NELSON-SMITH

ADVANCES IN POLLUTION CONTROL

Advances in Environmental Sciences

Edited by J. N. Pitts jun. and R. L. Metcalf. Vol. 1. Pp. 356. (Wiley (Interscience): New York and London, March 1970.) 150s.

THE recent explosion of interest in pollution has produced many new popular and scientific journals, as well as a host of books. In most branches of science we have "Annual Reviews" or "Recent Advances", and the volume considered here indicates that pollution will also have its multi-volume series. There is no indication, however, of the frequency with which new volumes will appear. If this means that publication will only take place when enough new material is available, the series will be welcomed by scientists if not by librarians, who may find it difficult to budget for an irregularly appearing and rather expensive periodical.

The editors are well chosen for their task. Professor Pitts is an authority on air pollution, with particular experience of photochemical smog. Professor Metcalf is an entomologist, with an international reputation in insect control. Unfortunately, they do not seem to have decided exactly for whom their series is intended. They themselves have contributed, as an introduction to their first

volume, an "Outline of Environmental Sciences" which is a useful summary which might have appeared, with little modification, in one of the British quality Sunday newspapers.

The other papers are of an uneven standard, and will appeal to readers with very different backgrounds. Thus the paper on the role of the American federal authorities in pollution control, by John Tunney, a member of congress, is purely administrative, though it sketches in the background against which scientists will have to work. Professor Kruse of Johns Hopkins University gives an account of the problems relating to American water supplies. This contains information which might be difficult to extract quickly from the literature, but there is little information which has not been described before, though the account could be valuable to non-scientists.

On the other hand, other articles assume that the reader has considerable chemical knowledge. Dr Edgar R. Stephens deals in detail with the peroxyacyl nitrates (PANs) in photochemical smog, and one of the longest papers, by Dr James N. Pitts, considers the importance of singlet molecular oxygen as an environmental oxidant, perhaps explaining some of the anomalies considered by Stephens. This latter paper contains much that will be incomprehensible to any except a specialist in the author's own field.

Not all the articles are particularly relevant to present-day conditions. Thus Dr Theodore E. Brenner of the Soap and Detergent Association devotes 50 pages to an account of biodegradable detergents. None of the data included is less than four years old. Most countries solved the "detergent swan" problem some years ago, and the facts are already included in standard textbooks. It is disappointing to note that there is no mention here of the current worry about eutrophication, particularly by phosphates, from modern, biodegradable, detergents.

Future volumes in this series may serve a useful purpose. Volume one suggests that the title "Advances in Environmental Sciences" is well chosen, instead of the alternative "Recent Advances" used in some comparable publications.

K. MELLANBY

PESTICIDE JOURNAL

Pesticide Science

Vol. 1, Nos. 1 and 2. Two-monthly. (Society of Chemical Industry: London, 1970.) Members 80s; non-members 160s per volume. (Per issue, 27s 6d.)

WITH sources of scientific information proliferating rapidly, the principal justification for the appearance of any new journal is that it will enable work to appear under one cover which hitherto has been distributed widely but thinly in numerous other journals. The more interdisciplinary a subject, the greater the tendency for this fragmentation to occur. The problems so created are well illustrated by those of workers in the highly topical and important subject of pesticides, for a balanced approach to this broad-spectrum discipline requires the cooperation of chemists, biochemists, soil scientists, mathematicians and biologists, as well as the special skills of industrialists familiar with practical and financial aspects of the manufacture, field application and commercial formulation of pesticidal substances.

Pesticide Science is published by the Society of Chemical Industry, a society which, by the establishment several years ago of a Pesticides Group, has already done much to encourage an integrated approach to the study of pesticides. The society is also well known for the *Journal of the Science of Food and Agriculture* (which often contains articles on crop protection chemicals) and for the pesticide sections of the *Reports on the Progress of Applied Chemistry*. Its experience is reflected in the quality of the editorial board of the new journal—D. Woodcock, J. K. Eaton,

C. G. L. Furnidge and A. J. Low are four eminent members of the board, selected for mention here because they represent distinct yet overlapping interests in the field of pesticides. The new journal considers for publication work relating to the production and use of pesticides, including those used in veterinary and public health. It also accepts articles covering the ecological and economic implications of their use. Papers in the first two issues of volume one do indeed cover a wide range of interests. It is, however, noteworthy that, while the effect of pesticides on organisms receives attention in several excellent articles, these first two numbers do not seem to do full justice to the complementary subject of the effect of organisms on pesticides. Yet such practically important matters as field performance, persistence, safety and selectivity of action are frequently dependent on the rate and the route a substance is metabolized. The editorial board of *Pesticide Science* undoubtedly recognizes this fact, and it is to be hoped that this apparent weakness in these first two issues is a consequence of pure chance, rather than to the absence of the word "metabolism" from the list of subjects which authors are told will be considered for publication.

With this one reservation, *Pesticide Science* promises to be a valuable new medium both for disseminating and for acquiring information on this rapidly expanding multidisciplinary subject.

KENNETH HASSALL

FIGHT THE GOOD FIGHT

The Ecologist

Edited by E. R. D. Goldsmith. Vol. 1, No. 1. Monthly. (Ecosystems: London, July 1970.) 4s per issue; 40s per annum.

THE bandwagon of environmental crusaders has had the brakes on lately, in Britain at least, but the publication this month of the first issue of *The Ecologist* promises a further lunge forward into new seas of effluent and deserts of dereliction. The magazine is by no means the detached and cautious scientific review that its title might suggest; indeed, insofar as it deals with ecology at all, *The Ecologist* dwells in a man-centred ecosphere and largely in those parts of it which man is supposed to be damaging beyond repair. What the editor, Mr Edward Goldsmith, is anxious to communicate is "the fact that there is a serious emergency", to be attacked fundamentally by checking the growth of population and by dispelling the myth of unrealistically high standards of living.

To this end, Mr Goldsmith has set up his own publishing company, Ecosystems Ltd, which is producing 60,000 copies of the first issue of *The Ecologist* for sale on the bookstalls or by subscription. In the contributed articles, environmental hypochondria is kept well under control. Professor R. Lindsay Robb, for example, argues the case for closer links between medicine and agriculture, suggesting that since both practices are concerned with human welfare they should be controlled by a common ministry. Mr Robert Allen, the assistant editor, also writes illuminatingly about the conflicting interests of the Eskimos and the oil companies in Alaska.

Some of the editorial comment, however, is on less firm ground. "Organisms that obtain mastery over their environment become over-specialized"—from which it is paradoxically made to follow that "they are at the mercy of the slightest environmental change that might create a situation to which they no longer have the means of adapting". Another item deplores the amount of money invested in art, in comparison with the difficulty of raising cash for conservation, and talks of "pseudo-concepts" of which "one of the most pernicious . . . is anthropocentric evaluation". This aggressive creed, coming from a magazine which is called *The Ecologist* but whose subject matter is principally man himself, may seem just a little surprising.

ROBERT MAYCOCK

Short Notices

The Origins and Growth of Modern Education. By Elizabeth Lawrence. Pp. 393. (Penguin: Harmondsworth, April 1970.) 10s.

MODERN educational ideas are not modern at all—they owe their heritage to the Romans, and their line can be traced unbroken through the Roman, Renaissance and Victorian eras. Elizabeth Lawrence, who has investigated the pedigree of "progressive" educational ideas with all the thoroughness of a genealogist, supports her theory with so many quotations that they take up more space than basic text. Twenty-five centuries of educational thinking are packed into the book, and educationalists from Socrates to A. S. Neill of Summerhill school play their part in the lineage. Although entrenched opponents of progressive education are unlikely to be won over by appeals to history, this book provides a useful compendium of educational quotations.

Scienza e Tecnica. Annuario della EST, Enciclopedia Scienza e della Tecnica. Pp. 566. (Mondadori: Milan, 1970.) 14,000 lire.

THE third in this series of scientific yearbooks maintains the outstanding qualities of its predecessors, notably in the eminence of its contributors and the excellence of the design and illustrations. The section on space, for example, contains articles by Dr Donald Rea of NASA on the exploration of Mars and by Dr Vladimir Kurt of the University of Moscow on that of Venus; there are also articles on the exploration of Jupiter and the outer planets, the launch system for the Apollo missions and the guidance and propulsion of space vehicles. The other sections of the yearbook, all of them of equal or nearly equal merit, are devoted to astrophysics, geophysics, the environment and philosophy of science. Even at 14,000 lire (£9 7s) the book is of good value.

The Wild Mammals of Malaya and Offshore Islands, including Singapore. By Lord Medway. Pp. xix + 127 + 15 plates. (Oxford University Press: London and Kuala Lumpur, June 1970.) 125s.

IN the states of Malaya and the adjacent offshore islands, including Singapore, it is illegal to capture or kill the Javan and Sumatran rhinoceroses, the apir, the pangolin, the binturong, three species of gibbon and the slow loris, and there are also several other species of wild land mammals out of a total of 199 in the region that are protected in some way. It would be wise therefore for the naturalist intent on a game hunt to read this book, which should give him sufficient clues to an animal's identity—a brief description is accompanied by notes on distribution, habits and life history, and there are handsome illustrations by Mazli Matsom and Hamidah Suhaimi.

The Royal Botanic Garden Edinburgh, 1670–1970. By H. R. Fletcher and W. H. Brown. Pp. xvi + 309 + 20 plates. (HMSO: Edinburgh and London, 1970.) 72s.

STUDENTS of the history of science whose appetite for botanical memorabilia was whetted by the recent article in *Nature* on Edinburgh's Royal Botanic Garden (226, 904; 1970) will find the full story of three centuries of floristic endeavour in this scholarly book. This is the story of the development of a forty foot square physic garden, founded in 1670 by Andrew Balfour and Robert Sibbald, into seventy-five acres of plants, greenhouses, exhibition areas and research facilities. It is also part of the story of botany's disengagement from medicine and its emergence as a science in its own right, as each new keeper and curator brought new plants and ideas to Edinburgh. The text is enhanced by a fine collection of plans and pictures which illustrate many phases of the garden's growth.

Correspondence

The Fly in the Fourier

SIR,—Long before the publication of my heresy, or *odium theologicum* as it has been termed (*Nature*, **226**, 404; 1970), I realized that there would be reaction from the Establishment; however, I did not expect that this would sink to the level of an anonymous report, cited above, written, apparently, by one unversed in the pitfalls of Fourier analysis. The crystallographic “nuances” referred to are not such at all, but truisms well known to experienced structure analysts. The author of this report appears to be so stunned by the fact that someone could have the temerity to question evidence which has been presented in support of a DNA structure that he has taken leave of his objectivity. Your readers should refer to the original papers (*Science*, **165**, 1091; 1969; **167**, 1693, 1694, 1694, 1700; 1970) and not rely on your reporter’s eclectic treatment of them. Thus, he states, referring to electron density difference maps: “These make the best of the data”, a statement which could be made only by one unfamiliar with the details of this technique. He repeats the fiction that there was misrepresentation of earlier results by omission of reference to difference maps, when, in fact, all parties agree that these contain no more information than do observed and calculated maps, which were found in 1991, above. He characterizes the letter by Crick (above, 1694) as an “olympian boot”, but is so untutored in the nature of diffraction that he is unaware of an egregious misconception of basics in that letter (pointed out in 1700, above) which effectively rendered that boot imperceptible. He also appears to agree with Crick’s view that if I am dissatisfied with the existing “canonical” DNA model I should employ my energy in attempts to construct satisfactory alternative models. But this is not the issue: it is rather like expecting someone who reacts unfavourably to an inadequate production of *Die Götterdämmerung* to mount his own ideal production. The real point, which your reporter so cunningly evaded, is whether the various electron density functions which have been presented as proof of a particular DNA structure do, in fact, constitute proof of that structure. The answer to this question surely should be made by “the trade” with its “crystallographic dialectic”, and not by workers in an unrelated discipline.

Your reporter’s view appears to be that because “the innocent bystanders” in “the outside world of molecular biology” do not understand the recondite world of X-ray crystallography, it would seem best for them to ignore the results of experiment, and believe only what they wish to believe on emotional grounds. This is indeed true innocence.

Yours faithfully,

JERRY DONOHUE

Department of Chemistry,
University of Pennsylvania,
Philadelphia, Pennsylvania 19104, USA.

This letter has been shown to the author of the article concerned, who replies as follows:

Dr Johnson on a celebrated occasion allowed a hot potato to fall from his mouth onto his plate with the words, “Many a lesser man, sir, would have swallowed that”. Evidently this view does not commend itself to Professor Donohue, for he has swallowed his hot potato. His letter, like his reply to his critics (*Science*, **165**, 1700; 1970), reiterates, but does not add to his arguments, and does not answer the charge of biased presentation of data—the failure to mention the part of an alternative structure

which does not fit the data, the use of electron density contour intervals so wide as to vitiate any inferences, and so forth. Nonetheless, Professor Donohue has shifted his ground. After thundering from the rooftops to an awestruck multitude the dreadful (if uncontested) truth that the structure of DNA has not been rigorously proven, he now—a trifle disingenuously, as it seems to me—belabours me for my indelicacy in intruding into a private rift within the crystallographic family, which should not be exposed to the vulgar gaze of the scientific *canaille*. While adopting a posture of defiance in the face of the Establishment, he utters a plea to be judged only by “the trade” or, as it is more aptly termed, the crystallographic Establishment. For the benefit of those readers who flagged before reaching the peroration of Donohue’s article (*ibid.*, 1700), I quote: “I did not mean to imply that the X-ray data for DNA could be fitted just as well by a model with alternative base-pairing. What I said was ‘The Fourier method of structure refinement has in fact contributed nothing toward either the proof of that structure nor toward the elucidation of its details’.” A modest claim, perhaps, and of a truly theological character.

The essential issue, however, was whether Donohue’s strictures can be said to impinge on molecular biology at large, and my argument—though as Donohue rightly implies readers can take it or leave it—was that they do not, because of the bulk and variety of the evidence on base-pairing in both DNA and RNA, and now indeed because of his failure, despite, one must suppose, fairly strenuous efforts, to produce an alternative pairing scheme that fits the data.

I am resigned to the eternal shame of being pilloried, in company with Crick, for my inadequate grasp of basic principles of X-ray diffraction. As to the difference Fourier maps, however, and what is agreed by “all parties”, I would merely direct readers’ attention to the view expressed by four of the parties (*ibid.*, 1693). Though as for *Götterdämmerung*—Professor Donohue, I can only surmise, sees himself as Siegfried, but who, I wonder, will be his Hagen?

Bombs and Earthquakes

SIR,—On May 9, 1970, Dr D. S. Robertson wrote to the *New York Times* pointing out that two severe earthquakes had followed underground nuclear explosions. Since then there has been much uninformed speculation in the press as to whether the Peruvian earthquake could have been triggered by the French nuclear test at Mururoa Atoll on the previous day (May 24, 1970). Robertson¹ is reported to have stated that “it now seemed almost certain that the tests and quakes are correlated”. It is the purpose of this note to produce both general and statistical arguments which lead to the opposite view.

The general reasons depend on the following arguments: the energy put into the ground by the Mururoa Atoll test (a few kilotons in the atmosphere) would be very small compared with that generated by an earthquake of magnitude 4 of which there are an average of 10,000 a year. Tests in the atmosphere are poorly coupled to the ground and we estimate the French test on May 29 to be equivalent to a local event of magnitude not greater than 2.5 of which there are approximately 100,000 every year. If Robertson’s conjecture were correct it would seem that earthquakes would be far more likely to be triggered by other large distant earthquakes than by nuclear bombs, but we know of no evidence or suggestions that this occurs. Small local foreshocks and aftershocks which

often precede and follow larger earthquakes might be considered as examples of these sorts of phenomena, although we believe they are more likely to be part of the total mechanism producing the original earthquake, and in any case they are local, not distant. There is also the fact that, as we would expect, the French atmospheric nuclear tests on May 15, 22 and 29 were not detected by the Warramunga seismic array or to our knowledge by any of the other seismic stations in Australia. Our estimates lead us to believe that the ground movement it would cause in Peru would be far less than the random background movement (seismic noise) which is always present and certainly less than a magnitude 4 event in, say, California. Fairly large earthquakes are not uncommon in Peru; for example, a magnitude 7.4 event occurred on November 10, 1946, and 5.9 on July 24 and October 1, 1969. On any mechanism the time delay, of the order of a day, between the bomb and the explosion required by Robertson would be difficult to explain. Finally, we know that large underground nuclear explosions produce small local shocks² so we should not expect small poorly coupled atmospheric explosions to produce large distant earthquakes.

Statistical evidence has already been cited by Underwood, Cleary and Read³. They found that "the occurrence of large earthquakes in the few days following an explosion is no greater than the normal level of activity". As further evidence we wish to add the following statistical argument:

Assume that earthquakes and bombs are independently distributed. Then the expected number of "coincidences", λ , due to chance is given by

$$\lambda = (\text{No. of earthquakes}) \times (\text{proportion of bomb days})$$

There are forty earthquakes a year whose magnitude is 6 or greater. Since January 1964 there have been 350 nuclear explosions; that is, the proportion of bomb days is approximately 1 in 8;

$$\text{therefore } \lambda = 40 \times \frac{1}{8} = 5$$

On the average, we would thus expect five coincidences a year due to chance alone. The actual number of coincidences a year will be approximately a Poisson distribution with the following probabilities:

Number of coincidences a year	3	4	5	6	7
Probability	0.13	0.16	0.17	0.15	0.12

From this we see that 3, 4, 5, 6 or 7 coincidences a year are nearly equiprobable and that the probability of 3 to 7 coincidences a year is 0.73. This means that we could expect 3 to 7 coincidences to arise by chance alone about every 1.3 years and this is what Robertson seems to have observed.

Yours faithfully,

GORDON NEWSTEAD
MARGARET PILE

Research School of Physical Sciences,
Australian National University,
Canberra, ACT, Australia.

Announcements

University News

Dr J. G. Thompson, at present senior research fellow at Churchill College, **University of Cambridge**, has been elected Rouse Ball professor of mathematics, as from January 1, 1971.

R. Buckminster Fuller, a member of the faculty of the University of Southern Illinois, will join the **University of Detroit** for one year as visiting professor.

Professor Robert W. Steel, professor of geography at the **University of Liverpool**, has been appointed a pro-vice-chancellor of that university.

Dr D. V. Bugg, principal scientific officer at the Rutherford Laboratory, has been appointed to the chair of nuclear physics at Queen Mary College, **University of London**.

Professor S. J. G. Semple, professor of medicine at St Thomas's Hospital Medical School, has been appointed to the chair of medicine tenable at the Middlesex Hospital Medical School, and **Dr K. O. Kemp**, reader in structural engineering at University College London, has been appointed to the Chadwick chair of civil engineering tenable at that college. The following titles have been conferred: professor of cytochemistry, on **Dr S. J. Holt** in respect of his post at the Middlesex Hospital Medical School; professor of clinical anaesthesia, on **Dr M. K. Sykes** in respect of his post at the Royal Postgraduate Medical School; professor of planning studies, on **Dr P. D. Cowan** in respect of his post at University College London; professor of endocrine physiology and pharmacology, on **Dr J. R. Hodges** in respect of his post at the Royal Free Hospital School of Medicine; professor of crystallography, on **Dr J. W. Jeffery** in respect of his post at Birkbeck College; professor of theoretical computation, on **Mr P. J. Landin** in respect of his post at Queen Mary

College; professor of mathematics, on **Dr G. L. Watson** in respect of his post at University College.

Dr Clive Rosendorff, research fellow of the American Heart Foundation and the British Heart Foundation and visiting assistant professor at Yale University during 1969-70, has been appointed to the Otto Beit chair of physiology at the **University of the Witwatersrand**.

Appointments

Mr J. P. Graham, deputy director of research of the **British Coke Research Association**, has been appointed director in succession to **Dr G. W. Lee**, who retired on June 30.

Mr A. F. Kelly has been appointed deputy director of the **National Institute of Agricultural Botany** in succession to **Dr P. S. Wellington**, who becomes director on October 1.

Dr John W. Fitchie, deputy director of the Fighting Vehicles Research and Development Establishment, has been appointed director of the Transport Research Assessment Group at the Ministry of Transport's **Road Research Laboratory**, in succession to **Dr A. J. H. Hitchcock**.

Miscellaneous

Dr Irmgard Flugge-Lotz, Stanford University, has received the 1970 achievement award of the **Society of Women Engineers**, for her significant contributions to the field of fluid mechanics, in particular wing theory and boundary layer theory.

The president of the **Argonne Universities Association** has announced the establishment of AUA distinguished

appointment programme for service at the Argonne National Laboratory. Each year an award will be available to a qualified faculty member to spend a year at Argonne National Laboratory. A similar award will be available for a qualified Argonne staff member to spend a year at an AUA university of his choice. Selections will be based on outstanding scientific or engineering accomplishments. In addition to his normal support, each recipient will receive a merit award of \$5,000. Nominees must be from the fields of biology, chemistry, engineering, mathematics or physics.

Entries are invited from any British firm or individual for a national competition, sponsored by the **Royal Society of Arts** in conjunction with the **BETRO Trust** and the **Edgar E. Lawley Foundation**, which aims to show the value of innovation in helping Britain's export trade and balance of payments. Two prizes of £500 and two of £250 will be awarded for the best case studies, including the successful use of new designs, inventions or discoveries, which either have contributed significantly in this regard or will do so in the next few years. Further details can be obtained from the Royal Society of Arts, John Adam Street, Adelphi, London WC2N 6EZ.

At the twenty-sixth annual general meeting of the **Institution of Metallurgists**, **Professor A. G. Quarrell**, professor of metallurgy in the University of Sheffield, was elected president of the Institution, in succession to **Dr A. H. Sully**. Also elected were **Dr W. E. Duckworth**, director of research, Fulmer Research Institute, and **Dr H. W. Kirkby**, director of research, Firth Brown Limited (vice-presidents); **Dr E. G. West** (honorary treasurer); **R. J. Brown**, British Leyland (Austin-Morris) Limited, **A. McConnell**, Weir Engineering Industries Limited, and **Professor J. C. Wright**, University of Aston in Birmingham (ordinary members of council elected by the Fellows); **Dr E. R. Petty**, Sheffield Polytechnic, and **E. H. Watson**, British Steel Corporation (ordinary members of council elected by the Associates).

At the annual general meeting of the **Australian Academy of Science**, **Professor R. N. Robertson**, master of University House, Australian National University, Canberra, was elected president of the Academy in succession to **Professor Dorothy Hill**. Other members of the council were also elected: **Professor A. J. Birch** (treasurer); **Professor G. M. Badger** (secretary, physical sciences); **Professor A. K. McIntyre** (secretary, biological sciences); **Dr A. L. G. Rees** (secretary, international relations); **Professor S. T. Butler**, **Dr S. D. Hamann**, **Professor B. Y. Mills**, **Professor B. H. Neumann** and **Professor A. E. Ringwood** (ordinary members, physical sciences); **Professor W. H. Elliott**, **Professor Dorothy Hill**, **Professor G. J. V. Nossal**, **Professor W. P. Rogers** and **Professor R. O. Slatyer** (ordinary members, biological sciences). Six new Fellows of the Academy were also elected, in recognition of their outstanding published contributions to research in the natural sciences: **Professor E. J. Hannan**, Australian National University; **Dr Mollie E. Holman**, Monash University; **Professor D. O. Jordan**, University of Adelaide; **Dr J. F. A. P. Miller**, Walter and Eliza Hall Institute of Medical Research, Melbourne; **Dr W. C. Swinbank**, CSIRO Division of Meteorological Physics, Melbourne; **Dr G. K. White**, CSIRO Division of Physics, Sydney.

ERRATUM. In the article "Advantages of an Antagonist" (*Nature*, 226, 1199; 1970) two references were incorrectly cited. The correct citation for Obata *et al.* is *Exp. Brain Res.*, 4, 43 (1967) and that attributed to Werman *et al.* (*Life Sci.*, 4 2075; 1965) was actually due to Aprison and Werman.

International Meetings

July 21, Memorial Meeting in Memory of the late Professor Sydney Chapman, London (Press Officer, Imperial College of Science and Technology, College Block, London SW7).

July 27–August 7, Contemporary Optics (summer course), Rochester, NY (Contemporary Optics, Institute of Optics, University of Rochester, Rochester, New York 14627, USA).

Sabbatical Itinerants

In the hope of providing some practical assistance in the good cause of mobility between laboratories, *Nature* advertises the needs for housing of families about to take up periods of sabbatical leave. To begin with, no charge will be made for advertisements like this. It is hoped that a period of experiment will show what form these advertisements could most usefully take and whether they are effective.

Wanted: Furnished 4–5 bedroom house preferably near Orpington, Kent, or in South London area, for Canadian physicist and family (6 children), from September 1, 1970, until April 1, 1971. Please contact Professor L. Krause, 5 rue La Bruyère, 78 Versailles, France (telephone 951-5100), or c/o Dr A. E. Kiss, 14 Elm Grove, Orpington, Kent (telephone 66-20329).

Wanted: Furnished London house with four or more bedrooms for one year beginning September, by returning professor and family. Please contact E. Cumberbatch, Mathematics Department, Purdue University, Lafayette, Indiana, USA; after mid-August, Mathematics Department, University College, Gower Street, London WC1.

Wanted: Furnished 3-bedroom apartment in Paris, accessible to Latin Quarter, from October 1, 1970, to June 1, 1971. Please contact Professor J. J. Price, Mathematics Department, Purdue University, Lafayette, Indiana, USA; after mid-August, 53, Promenade des Anglais, Nice, France.

Wanted urgently: Furnished accommodation for Russian doctor, wife and 1 year old child in London with easy access to King's College, London. Prefer garden flat with central heating. Please contact Dr V. Lednev, Biophysics Department, King's College London, 26–29 Drury Lane, London WC2 (telephone 01 836 8851).

Wanted: Furnished house near western edge of London or suitably situated for feasible commute to National Physical Laboratory, Teddington, and/or University of Reading, from about September 1970 for approximately nine months for visiting fellow, wife, and two children (8 and 10). **Vacant or exchange:** Furnished house in Berkeley, 3 bedrooms, study, 2 bathrooms, well equipped kitchen, central heating, excellent view of San Francisco Bay, for same period plus summer 1971. Please contact Dr P. Concus, Lawrence Radiation Laboratory, University of California, Berkeley, California 94720, USA.

Vacant: 4 bedrooomed house in Surrey, 45 minutes from central London. Free accommodation in return for running the house (owner remaining). Would suit junior postgraduate with not more than two young children. Available now for 12 months. Please contact Dr D. H. Clarke, 18 Starrock Road, Coulsdon, Surrey, CR3-3EH.

British Diary

Monday, July 20

Dielectric Materials, Measurements and Applications (five-day conference) Institution of Electrical Engineers, in association with the Institute of Physics and the Physical Society, and the Institute of Electrical and Electronics Engineers, at the University of Lancaster.

The Mechanisms of Reactions in Solution (five-day international conference) Chemical Society, at the University of Kent at Canterbury.

Tuesday, July 21

Memorial Meeting in tribute to the memory of the late Professor Sydney Chapman, FRS (3 p.m.) in the Department of Physics, Imperial College, Prince Consort Road, London SW7.

Reports and Publications

HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one copy of NATURE each week is:

12 MONTHS (52 issues and 4 indexes)

Great Britain and Eire £14 0 0 each
United States of America (by air freight) \$48 each
Canada (by air freight) \$52 each
Elsewhere overseas by surface mail £14 0 0 each

(Charge for delivery by air mail on application)

*Shorter periods pro rata. (Minimum three months.)

What Future for the Social Sciences?

It is not an entirely indecent question to ask whether the social sciences will ever become respectable in the narrow sense in which the word is usually understood by academics. One difficulty, perhaps unavoidable, is that the objective of a great deal of social science must be to clarify matters of urgent importance to society. Inevitably, a great deal of research in the social sciences is therefore bound up with the necessary muddy problems of the real world. Whatever changes there may be in the pattern of the work of the Social Science Research Council in the years ahead, there is no danger that it will ever have to grapple, as the Science Research Council has had to do, with the task of making grant recipients more aware of the practical implications of what they do. In this sense, of course, respectability is nothing to be proud of. A more serious worry, not merely for the Social Science Research Council but for the rest of the academic world, is that the social sciences seem often to drift rudderless across the academic scene. Too much of what is done in the universities in the name of the social sciences is neither relevant to the great social issues of the modern world nor helpful in the development of a body of coherent understanding.

Why are the social sciences such a mess? One obvious difficulty is the sheer diversity of the problems to which solutions seem accessible. The grants awarded by the Social Science Research Council in the past year are a splendid illustration of this. At the University of Nottingham, for example, new grants deal with statistical forecasting techniques in economics and the methods of work of the Prices and Incomes Board as well as with studies of child development and urban practices of child rearing which are closer to the universities' traditional interests. Elsewhere are studies of women's fashions, "the microecology of selected hamlets and villages in eastern Botswana" and also a study of "the role of the headmaster". It would be wrong for outsiders to pretend to know that any of these projects does not deserve support—indeed, one of the most impressive features of the latest annual report from the Social Science Research Council (see page 648) is the way in which the council has faced head-on the difficulties which arise from the diversity of its parish and from the inevitable unpreparedness of its pensioners. Without saying much, the council quite rightly behaves as if its first task is to build up a social science community in Britain which is strong enough not merely to hold its head above water but to do so with some pride.

In circumstances like these, however, it is entirely proper to question the council's decision not to pursue a policy of selective support, at least for the time being. Two separate issues arise. First, should sup-

port for research in the social sciences be distributed in such a way that there is a chance that busy policymakers will be helped in their work? This is the argument of those who hold that the social sciences are potentially even more potent than technology as a means of making a better society. The trouble is that the argument puts the cart before the horse in assuming that the magic wand of money will make good ideas appear wherever it is waved. The council is right to reject this criterion for support. The second, more practical issue is whether the council should select a few areas on which to concentrate its efforts, either because these are fields in which good people are already hard at work or because there is reason to believe that further knowledge would bring particularly valuable results. This is a policy which the Science Research Council has been pursuing in the past few years with success but also at the expense of the sensitivities of some research groups whose interests do not coincide with those of the research council. The Social Science Research Council seems to take the view that the nature of social science research is still so poorly understood that selectivity would be premature. But is this really so? Might it not indeed be sensible, at this early stage in the development of social science in Britain, to single out the areas in which growth seems at once feasible and likely and to hope that these will become intellectual bridgeheads from which a better understanding may be built out.

The risks inherent in the present policy of diverse support are quite considerable. To begin with, there is the possibility that the talents of good people may be scattered on too many unrelated projects, some of which are trivial. Second, there is the danger that no single centre of academic activity will be large enough to sustain the momentum of a successful research programme. Third, there is the certainty that many of the projects now begun will turn out, some years from now, to sustain research groups with whom the council will by then be disenchanted.

The council's hankering after research institutes of its own is another cause for anxiety, however strong the special reasons for setting up the Industrial Relations Research Unit and the Race Relations Research Unit (at Warwick and Bristol respectively). Why should not activities like these, interdisciplinary though they may be, fit into the more familiar structure of a university? The council may be right to say, in its latest report, that university departments are bad at collaboration with each other, but that is no reason to give up trying to beat their heads together. And the advantages of using the existing machinery of the universities for carrying out interdisciplinary research programmes are that teaching and research

are more intimately linked and that the bright trained people who emerge from the research programmes are likely to be scattered widely within the university system as a whole. Given that the research council's chief aim at this stage must be education, it is hard to think that the rewards of particular interdisciplinary

research programmes can be so great as to transcend the normal machinery of the universities. To be sure, the Social Science Research Council may say, with justice, that the two units so far established are well integrated into the system. Outsiders, however, may regard them as bad precedents.

Towards a Better Apocalypse

THE first report of Mr Russell Train's Council on Environmental Quality is a judicious mixture of tub-thumping, political savvy, popular science and good sense. It has something for almost everybody, and even a special message from President Nixon which says that the report "represents the first time in the history of nations that a people has paused, sociously and systematically, to take comprehensive stock of the quality of its surroundings" (see page 654). The President goes on to congratulate himself and his colleagues in the Administration for what has been done already to give the environment pride of place in the new scheme of things—the setting up of the Council on Environmental Quality was the first sign of the way in which the wind was blowing—but this makes the message not merely an exhortation but a reminder, valuable, no doubt, that even Mr Train's council is in the last resort a part of the Executive Branch and not an appendage of the Supreme Court. Its first report would have been more persuasive if it had not been so openly political.

To look on the good side, the report has nevertheless several sterling qualities that should not go unsung. It takes a broad view. There is, for example, a sensitive discussion of the myth that flits from one dinner table to another to the effect that economic growth as such is a potential hazard to the quality of life. The simplest form of the myth derives from two unconnected considerations—the belief that all power stations produce hot water (the cause of thermal pollution as it is called) in proportion to their output of electricity and the belief that electricity production is a monotonically increasing function of the GNP. So, the argument tends to go as the hand-dipped candles burn low, more GNP means more electricity and therefore more thermal pollution. Mr Train's report points to an elementary but nevertheless important flaw in the argument—that it is quite possible to increase the GNP of a nation such as the United States by making it compulsory to fit anti-pollution devices to the exhaust systems of automobiles, for the GNP, after all, is measured by the prices of manufactures and other goods. The only snag is that investment in better mufflers is unlikely to lead as certainly to future economic growth as investment in, say, power stations. The point is well worth making, for there is a great need to make sure that people cannot wriggle off the pin that compels a choice between one desirable thing and some other. Mr Train's report is also to be admired for what it has to say about the use of land in

the United States (and there may in the long run be great value in the way in which the President has endorsed this part of the report). What the council says is simply that the way in which local communities finance their general expenses by means of property taxes provides many of them with a vested interest in the urban sprawl. The moral, plain enough for everybody to see, is that there is an urgent need for centralizing the regulation of land usage.

All these are thoughtful matters. One of the defects of the council's report is that much of it is also trivial. The usual discussion of the dangers of accumulating carbon dioxide in the atmosphere is, it is true, hedged around with qualifications, among which the discovery that carbon dioxide is soluble in seawater shines through as if it had not been known all these years that the balance between the carbon content of the biosphere, the atmosphere, the oceans and the carbonaceous rocks is dynamic and not static. The same sense of wonder permeates the council's complaint that only one per cent of the money spent on meteorological research is spent on attempts to understand "man's inadvertent modification of weather and climate". So what? Is there any sense in seeking to understand the effects of, say, major afforestation schemes on climate in the surrounding region without knowing much more about the behaviour of the atmosphere on the mesoscale? And if there is need to understand more clearly the way in which a city can influence its own climate, is it not best to begin by seeking an understanding of atmospheric motion on an even smaller scale? In other words, the council runs a serious risk of putting the cart before the horse in what it has to say about meteorological research. And in this context, it may well have overlooked the importance of the political aspects of the problem (in the broadest sense), for it may well be that New York has become intolerable in the summer because one small air conditioning set is having to work flat out so as to process the exhaust from several others. The time may have come when cooperative air conditioning is the only feasible solution. Unhappily, the coordination of local policy necessary to bring about such a state of affairs, or to prevent municipal pollution of rivers or the foolish littering of the countryside, will require much more in the form of political organization than the institutions set up in Washington in the past few months as devices for persuading voters that something is now about to be done to safeguard the environment. The council

could have done better than to provide a blanket endorsement for these devices.

And with all its reflectiveness, it could have looked more deeply at the international implications of what it wants to say. It is true, of course, that Mr Train goes much further than previous sponsors of reports on the environment in drawing attention to the simple proposition that the environment is ultimately indivisible. Unhappily, this leads the council simply to a discussion of the importance of "monitoring the world" as one chapter heading has it. Why so few American organizations recognize the great indelicacy of this point of view will be a constant mystery to those outside North America who are sometimes painfully aware that only the richest nations can afford to fuss over the environment as the United States has been doing in the past few months. Mr Train should perhaps consider how it must sound to populations now graduating from bicycles to motor cars to be told that automobile exhausts are such a serious nuisance that their use should be severely curtailed. There is a

danger that to populations now struggling with a GNP per head which is hardly more than one per cent of that in the United States, well-meant introspection about the virtue of economic growth may seem a form of self indulgent smugness. And too much exhortation about the need for controlling the growth of the population may seem like neo-colonialism to nations in which the infant mortality rate is still mediaeval and in which a willing pair of hands is the next best thing to a machine. In short, if the environment is one global piece, is it possible to detach separate problems of air pollution from problems of foreign aid? And by this test, does the \$4,000 million that the Administration has set aside for the control of water pollution (most probably inadequately) make up for what it has agreed with Congress not to spend on the conditioning of the rest of the world to regard pollution as an evil and not a necessity? At one point in his report, Mr Train acknowledges that there is a long way to go in the fight for a better environment. It is even longer than he knows.

Swords into Rubbish

THE Department of Defense in the United States seems to have a nasty flair for mishandling its stocks of nerve gases. Not so long ago, large numbers of sheep in Utah were accidentally killed. Not so long ago, the state of Washington was up in arms (so to speak) because of proposals to store nerve gas there. Now there are protests about the scheme for sinking a ship laden with rockets which contain nerve gas off the edge of the Continental shelf off the south-east coast of the United States. The small communities along the two routes which will be taken by the two trainloads of disused rockets seem to be seized either with anger or indifference, but for many people the whole affair is too much an illustration of how the military, in their handling of potential hazards to the lives of people, can combine immense mechanical efficiency with a failure to reckon in advance with public opinion.

This is why it may be important first of all to acknowledge that the disposal of the rockets now under way is probably a simple consequence of the decision earlier this year that the United States would abandon the use of biological weapons and even back-pedal on the use of chemical weapons, nerve gases and the like. That, at least, is one point in its own defence which the Department of Defense might have advanced against those who have taken the movement of the useless rockets as yet another sign of the belligerence of the Pentagon.

It is also almost certain that the method of disposal now being used is safer than any other that might have been devised. If the nerve gas, supposed to be that known as GB, had been in simple containers, it would no doubt have been possible to dispose of it chemically, by hydrolysis in caustic soda. The difficulty in the present operation no doubt stems from the way in which

nerve gas and rocket fuel are held together in the same container. Given the precautions which are being taken along the routes to the coast, there is little cause to fear an overt accident. It is also probable that if the integrity of the concrete cases in which the rockets are contained should somehow be destroyed 1,600 feet below the sea, both the nerve gases and the rocket fuels would quickly be rendered impotent. (The half-life of GB gas in water is reckoned to be about 10 days, too long for disposal near the turbulent surface of the sea but probably just on the margins of acceptability at 1,600 feet.) This does not fully answer the question why the military have not been more ingenious in working out some way of denaturing nerve gas rockets without having to dump them in the sea.

So why is there all this fuss? The complaint against the Department of Defense is simply that it has once again been exceedingly cavalier in its regard for international proprieties. Especially at a time when the United States is taking a part of the initiative in the development of international law to govern the seabed (in contrast with the high seas, see page 656), it is almost beyond belief that there should be mounted such a tactless operation as the mass disposal of nerve gas. That even the British Government—by no means a steady opponent of United States foreign policy—should have sent three scientists off to make an independent assessment of such hazards as there may be off Bermuda should be a sign to the United States of how seriously the incident is regarded elsewhere. And if there should be any doubt, U Thant, the Secretary-General of the United Nations, should have left the planners in no serious doubt of the importance of what they plan.

The simple truth is that the care which has no doubt been taken to make sure that the operation will be

carried out safely does not in any sense absolve the United States Government from the need to discuss what it proposes fully with other nations which have expressed an interest. The fact that there is at present no legal requirement for the United States to seek permission in this way is quite beside the point—the best way to encourage the adoption of internationally acceptable restraints is to behave with restraint in advance of the formalities. The fact that the present operation merely repeats what has been done before is also irrelevant—a great deal of international experience in the past few years has only gone to show that precedents are false guides when the susceptibilities of other nations are concerned.

100 Years Ago

MR. DARWIN AND THE FRENCH INSTITUTE

THE judgment of foreign nations gives the best clue to that of posterity; and it is therefore with peculiar interest that the countrymen of Mr. Darwin have watched the reception of his works in France and Germany. In the latter country his theory of the origin of species has been more or less completely accepted by those best qualified to judge, including men like Gegenbaur and Haeckel; and it has produced a complete literature of arguments and facts "für Darwin," without encountering any very serious opposition. In France, the truth of the theory is far less extensively admitted, and has been lately the subject of prolonged discussion in the Academy of Sciences. The debate on Mr. Darwin's claims has now been adjourned for three months, but so far as it was reported in our last number it furnishes much ground for reflection.

At the present time, Imperial France is, perhaps, the most conservative in science of any country in Europe. It is not, therefore, surprising that, with a few exceptions like M. Claparède, French naturalists refuse to accept the theory of Natural Selection, and do not see (as others, and notably the Germans do) that it has already made a new epoch in human knowledge. Some, like M. Robin, object that it is not "demonstrable," and therefore not scientific at all; as if gravitation or the atomic theory had been, or could ever be, demonstrated like a proposition of Euclid. The Darwinian theory offers an explanation of acknowledged facts by the help of others equally indisputable, and it will only be "disproved" when it ceases to furnish an adequate explanation, or is superseded by a more simple and equally sufficient hypothesis. Meanwhile it fulfils, at any rate, one object of every theory, by stimulating research in all directions, and awakening new interests for the fresh investigations which it suggests.

From Nature, 2, 309, August 18, 1870.

OLD WORLD

RESEARCH COUNCILS

Social Science Emergent

THE annual report of the Social Science Research Council for the year ending on March 31 this year is a reflective document, containing not merely a record of how the council spent £2·27 million during the year (an increase of 65 per cent in a year) but also a thoughtful definition of the problems which arise in making research policy for the social sciences. To its credit, the council is the first to draw attention to the comparatively high cost of spending its money—£242,323 or close on 11 per cent of the total budget went on administration in the financial year just past. The council says that its comparatively high rejection rate (among research councils) is a part of the explanation, but there is also substance in the council's view that in present circumstances, there is bound to be a greater variety of opinion on the merits of particular research proposals than in other fields of inquiry. In practice, the council spent more than half of its budget on the support of postgraduate education in the social sciences, mostly in the form of studentships tenable at British universities. Research grants, as such, used up £0·86 million, compared with £0·58 million in the previous year.

The council's report says the open-ended character of social science research is no doubt part of the reason why potential applicants have found it hard to formulate convincing proposals for research projects. The council's goal is a research programme which promises a substantial advance of knowledge of "a connected series of social phenomena". Although the council rather wistfully regrets that much of its load of paper-work derives from the lack of scale and continuity which characterizes research in the social sciences, it acknowledges that a part of the trouble may be that social scientists are not yet as skilful as the natural scientists "in formulating viable research programmes". The council also says that new projects in the natural sciences can often be commended indirectly by the willingness of an existing institution to accommodate new work, and that the social sciences have not yet reached the point at which a substantial group of people in one place, possibly centred around equipment of common usefulness, can lend a pattern to the development of research.

On the development of criteria for deciding which projects to support, the council reaffirms its view that research grants cannot be distributed according to principles such as the urgency of the underlying issues of social policy. At the present stage in the development of the social sciences, the council says, nobody can say with certainty that a well designed piece of research will be irrelevant to the development of understanding in any discipline. The Social Science Research Council seems to have been encouraged in this view by the advice of the Science Research Council that the less radical policy of singling out areas of research within which work should be encouraged is not feasible so long as the difficulties and rewards of social science research are comparatively ill understood. That said, the council is not unwilling to single out particular research problems and has indeed, in

the year past, set up two research units in industrial relations and race relations.

One of the tendencies apparent in the council's report is a hankering after research units. The council says that the needs of interdisciplinary research are not always met within the structure of university departments and that "it is hard to avoid the impression that when any serious work needs to be done, there are powerful forces that drive the activity back into a series of separate departmental enclaves".

The 40 per cent of the SSRC budget spent on research grants was in 1969-70 awarded to 173 applicants, which implies a rejection rate of almost exactly 50 per cent and more money for fewer successful applications than in the previous year. The open-endedness of the social sciences as such is reflected in the way in which some of the council's money is spent on long-term open-ended research projects such as that under Professor J. Parry Lewis at the University of Manchester intended to devise a comprehensive urban simulation model. Support for postgraduate teaching is the most rapidly growing part of the council's budget, but the council is evidently prepared to look sceptically at the value of conventional PhD courses in the pattern of its activities.

LAW SUITS

Animal Research

THE settlement was announced this week of a libel action brought by Mr John Bleby, Director of the Laboratory Animals Centre of the Medical Research Council, against the weekly magazine *Titbits* and the British Union for the Abolition of Vivisection. In November 1968, the magazine apparently published an article about medical experiments with animals which included a photograph of Mr Bleby and allegations of cruelty to animals. The British Union for the Abolition of Vivisection was involved when it displayed in its premises in Whitehall an enlarged photocopy of the article. In the settlement out of court this week, *Titbits* and the British Union paid substantial damages to Mr Bleby and the union also agreed, in a statement in open court, to display in the windows of its Whitehall office a copy of the full report of the proceedings in court which is to be published in *Titbits*.

The chief function of the MRC's centre is to make animals more readily available to research laboratories, but it also gives advice on how to keep and house animals. One result of the centre's work is that by improving breeding techniques, inbred strains of animals can be bred more efficiently and fewer animals need to be bred for experiment than under a purely random system. Apart from research on breeding techniques, no medical research is carried out at the Laboratory Animals Centre.

SEISMOLOGY

England Shakes

LAST Sunday evening's earthquake which startled people in the northern counties of England would have gone unreported if it had occurred in one of the world's recognized earthquake danger areas. But by British standards with a magnitude on the Richter scale of

between 4.5 and 4.75, as estimated by the seismological unit of the Atomic Energy Authority, last Sunday's event rates as one of the largest to have been recorded. It was felt in Cumberland, County Durham, Westmorland, Lancashire and Yorkshire, and as *Nature* went to press the location of the epicentre had been narrowed down to the neighbourhood of the town of Kirkby Stephen on the Westmorland-Yorkshire border.

According to the geology department at the University of Durham, which makes a speciality of the study of British earthquakes, the earthquake on Sunday probably originated in either the Craven fault belt or the Dent fault, which form the southern and western boundaries respectively of the Askrigg block, named after the village of Askrigg in Wensleydale. The blocks in this area have been stable in themselves since the Carboniferous, of the order of 300 million years ago, so that faulting has tended to be concentrated at the boundaries. The Durham group are now looking up the records of an earthquake which geologists with long memories recall as having occurred in the same area in 1932.

Modern geologists will be pleased that the theory of continental drift and sea floor spreading can be implicated, although in a roundabout fashion. The likely explanation of Sunday's earthquake is that it was an adjustment of the crust related to the subsidence of the North Sea basin that has been going on since the Tertiary. It is then argued that the North Sea basin itself may be the result of the pressures that occur at continental margins as a result of sea floor spreading. An alternative explanation of the earthquake, less favoured at Durham, is that it was a dying whisper of the Alpine orogeny, the process responsible for Swiss scenery.

The depth at which the earthquake occurred is not yet known, but a quick look at the seismograph records suggests something like ten to fifteen kilometres. The surprisingly wide area over which tremors were felt suggests, however, a greater depth, possibly twenty kilometres, which places the earthquake only just within the base of the crust. When readings are received from stations outside Britain, it will be possible to fix the depth more precisely. A fault plane solution, giving the direction of movement that occurred, will be attempted at Durham. In the meantime, this earthquake was a nice reminder that Britain is not as seismologically quiet as people believe—in the past year or two there have been several earthquakes in the Bangor area with a magnitude of up to 4, probably associated with the faulting along the Menai Straits.

CHEMISTRY

Removing the Boredom

by our Education Correspondent

CHEMISTRY students at the University of Sussex may take part next session in trials of a scheme designed to make undergraduate chemistry courses more attractive and less boring. The scheme, outlined by Professor Colin Eaborn in the current issue of *Chemistry in Britain*, will be run alongside conventional chemistry courses. Its chief aim is to take some emphasis away from formal lecture courses and to base the degree on creative research work.

Professor Eaborn, who is chairman of the science faculty board at the University of Sussex, points out

that the demand for places in chemistry departments of many British universities has been falling steadily during the past few years, and most universities now admit students who achieve only the minimum entry qualifications. "It is my impression," Professor Eaborn says, "that many students, especially those with the more lively minds, find chemistry courses boring. I suspect that the major defect of existing courses is that they give the student little or no opportunity to exercise his originality, individuality and creative ability."

What Professor Eaborn suggests is that during the first or second year of a chemistry course, an undergraduate should be given a research problem which will be his chief concern from then on. At the same time, he should familiarize himself with the usual range of chemical knowledge either through existing lecture courses or through suitably modified courses. The research topics should be chosen according to two basic criteria: there should be a good chance that hard work will lead to results, and the research should draw on wide areas of chemistry.

As far as assessment is concerned, Professor Eaborn believes that in addition to a final thesis, there should be taken into account a student's approach to his work, as shown by literature surveys and essays directly or indirectly related to his project. "If we could produce a distinctly better graduate by abandoning assessment altogether I believe we should be prepared to do so," Professor Eaborn suggests, "but my own view is that degree classes based on the course I propose would be at least as accurate as the present examination grades as indicators of future achievement."

The chief attraction of such a course is that an undergraduate would be motivated to learn by his own reading, which would be stimulated by enthusiasm for his research activity. But the chief drawback is the cost in terms of teaching time and laboratory equipment. Calculations carried out at Sussex suggest that an undergraduate might cost between one-third and one-half as much a year as a research student. Professor Eaborn points out, however, that university plans for the 1972-77 quinquennium must be formulated during the next twelve months or so, and that this is a good time for chemists to seek additional funds "for a bold scheme which might transform the attractions of chemistry as a university subject".

The chemistry faculty at the University of Sussex has decided to try the scheme out on a few students next session, but final approval must first be obtained from the Senate.

COMPUTER SCIENCES

Quickening Pace in Software

A NEW recruit to the band of software companies was recorded last week with the decision of GEC-Elliott Automation to set up its own subsidiary organization. This follows only months after the creation by ICL of a separate software company, Dataskill, and adds further weight to the notion that the software business has already overtaken the hardware side as the chief money spinner in computing.

It seems that the shortage of trained programmers, however, played an important part in convincing GEC-Elliott that the time was ripe to commit resources to a new company—its first new systems company since

the formation of the group nearly two years ago. One innovation will be a system of data terminals on line to the computer centre through which it is hoped that women confined to the home will be able to continue their work as programmers. The company will have two large computers at its disposal and will, to begin with, operate with 40 or 50 people.

The latest figures from ICL indicate that expenditure on software is increasing by something like 25 per cent a year. It is estimated now that more than 40 per cent of the total expenditure on computing in Britain is swallowed by up software, which amounts to a national turnover of over £200 million. One of the complaints of the much lamented Select Committee of the House of Commons was that government departments are reluctant to make efficient use of the facilities of software houses because of the requirement that they must make full use of their own permanent staff.

Although the Select Committee was disbanded in June, Mr Eric Moonman and two of his fellow ex-MPs are determined, it seems, that the hard work of the subcommittee investigating the computer industry should not go by default. They intend to publish an account of what the committee would have reported to parliament had Mr Wilson held back the general election until next year. This will take the form of a collection of articles combined into two separate volumes. Mr Moonman will be writing about the international posture of the British computing industry, Mr Eric Lubbock will be concerned with the government's purchasing policy for hardware and Mr Arnold Gregory will write about the impact of computers on education. The three non-parliamentarians involved are Professor S. Gill of Imperial College, London, who will contribute on the impact of computers on telecommunications, Professor A. Douglas of the London School of Economics who will write about the government's purchasing policy for software and Mr F. Lamb, also of LSE, who will contribute on the government's support for research and development.

REGIONAL MUSEUMS

University Takeover

THE Swansea Museum, once described by Dylan Thomas as a museum that ought to be in a museum, seems now to be well on the way to oblivion under the shadow of the University College of Swansea. At a meeting at the Royal Institution of South Wales at the end of July, the membership of the institution and their proxies turned out to be in favour of a proposal that the University College should in future pay for the cost of the upkeep of the museum and that, with luck and at the beginning of the new university quinquennium, the university might provide extra staff. At the meeting at which this proposal was accepted, several members appear to have spoken against the partnership with the university, some on the grounds that not sufficient effort has been made to preserve the independence of the museum and that, in any case, if there has to be a benefactor, it should be the Corporation of Swansea and not the university.

The new arrangement will give the university the lease of the museum, but the university agrees "for as long as the Royal Institution continues in existence" to set aside some space "such as a room or part of a room" for the administration of the institution.

The future of the museum which the Royal Institution of South Wales is best known for is not entirely clear from the resolution accepted by the membership in July, but it does appear that there will be a joint management committee and that the university may in due course appoint a director. Like many similar institutions, the Swansea museum has suffered since the Second World War from the discovery that its once handsome endowment is now hardly sufficient to pay for electric light and heating. In successive attempts at modernization, the museum has indeed been made to seem less interesting. The banishment of the stuffed elephant that used to guard the doorway was no doubt an acknowledgment of the need for modernization, but it seems not to have been followed by a hardheaded appraisal of what the function of a museum might be in a modern industrial city.

WATER RESOURCES

Water for Wales

THE control of water resources in Wales is still too fragmented in spite of some recent reorganization, and the authorities involved take too narrow a view of their responsibilities, according to the Welsh Council. In its advice to the Secretary of State for Wales (*Report on Water in Wales*, available from the Welsh Council, Cardiff), the council complains, for example, that the river authorities lack positive powers to advance the wellbeing of areas in which reservoirs are built. A more coordinated approach could be taken instead by a new body, a Water Development Authority for Wales, which should have wider responsibilities than the existing river authorities and the Water Resources Board to build and regulate reservoirs and to develop their use for recreation. The authority could be financed, the council suggests, by levies on water supplied to the various water undertakings, and, being a commercial organization, it should be able to deal more satisfactorily with the often tricky negotiations for compensation for land acquired for reservoirs.

The council does not consider desalination a practical alternative to conservation and storage of river water, but points out the advantages of estuary storage schemes which, it believes, are less likely to raise objections in Wales than are upland reservoirs. It asks for the early completion of studies on the feasibility of the Dee Estuary for water storage, and also for the initiation of a study into possible storage schemes in the Severn Estuary and elsewhere. The council points out, however, that estuary storage is unlikely to make a contribution until the end of the 1970s, and even then, some upland reservoirs will still be needed.

Reservoirs in rural areas in Wales could, the council says, be made profitable to the communities if they were properly developed for recreation. The council also emphasizes the need for careful siting of buildings, and it comments that some of the reservoirs recently built in Wales might have fitted more satisfactorily into their surroundings if the dams had not been of stark white concrete.

The government will now consider this report alongside the forthcoming regional study from the Water Resources Board and reports which are due from the Central Advisory Water Committee and from the Sports Council.

ANIMAL HEALTH

Cows Not Well

THE first incidence of acariasis in bees was reported in Romania last year, and colibacillosis of pigs was confirmed in Fiji. Camels in Somalia were suspected to have anaplasmosis, but bluetongue was no longer recorded in India. Once more the health of the world's animals has been analysed, tabulated and published by the Food and Agriculture Organization as the *Animal Health Yearbook*. The information about foot and mouth disease shown here is part of a more comprehensive table depicting the incidence of the disease in Europe, together with each country's vaccination policy. From South America, a success story is recorded in Argentina, where vaccination has contributed to the establishment of the area south of parallel 42 as a disease free zone. Less happily, throughout the continent last year several new sub-types of foot and mouth virus were reported.

Vaccination may be CP, compulsory periodically; CO, compulsory in outbreak areas; V, voluntary; and P, prohibited.

* In Austria vaccination is prohibited unless officially ordered.

HUMAN ECOLOGY

Man under the Microscope

MAN's relationship with his environment, in all its multidisciplinary glory, has been taken under the wing of the Commonwealth Human Ecology Council (CHEC), which was set up officially last November. It has come into the limelight with the announcement of plans for a Commonwealth conference on development and human ecology. Joint sponsorship of this conference, to be held in Malta next October, is the first major project of the council, which has the ambitious aim of seeking ways to encourage Commonwealth governments to avoid the mistakes of the past when planning future developments—agricultural, medical, economic or whatever.

This wide ranging aim is reflected in the composition of the executive committee, which includes Dr E. B. Worthington of the International Biological Pro-

gramme. Professor H. Bowen-Jones, director of the Centre for Middle Eastern and Islamic Studies at Durham, and Mr J. Owen Jones, director of the Commonwealth Bureau of Agricultural Economics. The chairman is Mr A. S. H. Kemp, secretary general of the Royal Commonwealth Society, exemplifying the belief that the Commonwealth is a valuable unit in which to pursue the study of human ecology.

CHEC evolved from a committee on human nutrition in the Commonwealth, which, in the 1950s and early 1960s, had such active members as Professors B. S. Platt and R. A. McCance looking for a closer relationship between agriculture, medicine, nutrition and education. This committee conceived the idea of a pilot case study of a small Commonwealth region so that hard facts could be established on an ecological basis. From this idea grew a study of Malta, which the Government and Royal University of the island began in 1966. To complement the activities in Malta with expertise and advice CHEC came into being as a non-profit-making company.

So far the medical side of the Malta project has involved a survey of the physical development of children with respect to nutrition, and a survey of attitudes to health in rural communities. A socio-economic survey is under way, and at the planning stage are surveys of soil and water balance needs, agricultural and food resources, education and physical planning and urbanization.

CHEC hopes that the findings of this and future projects—none are at present in the pipeline—will not only help planners in the regions concerned, but will also be applicable to similar regions in developing areas of the world such as Africa and India. CHEC and the other bodies which are supporting its activities—Unesco among them—feel that this could be a way of providing guidelines for development in harmony with the environment. The first fruits of these grand designs will be made known at the conference in October. With the experience of the Malta project in mind, it has the object of “examining problems of satisfying essential human needs while establishing an ecologically sound balance between man and his environment”.

ASSOCIATIONS

New Image for ANZAAS

SOCIAL responsibility is rapidly becoming a catchword among scientists in Australia and New Zealand. Not only has the Australia and New Zealand Association for the Advancement of Science adopted the aims of the social responsibility movement and embodied them in its new constitution, but the association's new-style magazine *Search* is anxious to publish articles concerned with the social and economic consequences of science and technology.

The new constitution of ANZAAS, which was proposed last August by a committee under the chairmanship of Sir John Crawford, is essentially a response to the growing dilemma which faces many such organizations. Specialized societies have steadily been taking over the association's role of bringing together scientists for the exchange of information and news, and ANZAAS was forced either to change its aims and functions or to do nothing and fade into obscurity. The aims set out in the association's new

constitution deftly solve the problem of bringing its members together to pursue a common cause—to ensure that science and technology are used for social good—and at the same time they should help to promote science in an atmosphere which is becoming increasingly hostile to scientific development.

The aims of ANZAAS, as stated in the new constitution, are “the advancement of knowledge by bringing together scientists of all types and occupations so that they may interchange information and ideas, and making the public aware of what science is, what scientists do, and of the applications and implications of scientific discoveries to their everyday affairs and those of the nation”.

Sir John's committee clearly saw the need for improved communications between members of ANZAAS for carrying out the new aims of the association, and it took a hard look at the ANZAAS journal, the *Australian Journal of Science*. The first thing to be done, the committee decided, is to give the magazine more money, and to make it more topical and outward looking. The results were seen recently with the publication of *Search*, the new magazine of ANZAAS which has a completely different editorial policy from the old journal.

Mr J. B. Davenport, the magazine's editor, explained in an editorial that *Search* intends to publish review articles which should be comprehensible to scientists not working in that particular field, articles which deal with the social and economic consequences of science and technology, news and comment, and short research communications from scientists working in Australia and New Zealand. Science education will probably receive considerable attention in the magazine's pages, and the first issue contains articles on universities and research and the place of science in Australian education. *Search* is certainly a refreshing change from the *Australian Journal of Science*.

NATURE RESERVES

Mementoes of the Ice Age

A section of the famous “parallel roads” in Glen Roy near Fort William in Inverness, an area which has recently been purchased from the Forestry Commission and subsequently declared a national nature reserve by the Nature Conservancy. The three “roads” or terraces which run along the sides of the glen mark the former water levels of lakes which had been dammed by glaciers during the Ice Age. The highest terrace is at a height of 1,155 feet above sea level, the middle at 1,077 feet, and the lowest at 862 feet.

NEW WORLD

Congress Deaf to Prophecies

"THAT we are in a budgetary crisis no one can doubt; nor can one doubt that the crisis was foreseen; and that we did little five years ago when the crisis was predicted precisely in the National Academy of Sciences' report to your Subcommittee." With appropriate expressions of regret Dr Alvin Weinberg, director of the Oak Ridge National Laboratory, assumed last week the not wholly unpleasurable role of Cassandra before the House Subcommittee on Science, Research and Development, which has now completed four weeks of hearings on the issue of whether the United States should develop a national science policy.

In a brief but forceful statement, Dr Weinberg reminded his listeners of the forecast made in 1965 by the NAS committee, of which he was a member, that the basic physical sciences would face a major funding crisis because the agencies that had accepted responsibility for them were not at that time being permitted to expand. The committee had also recommended that the National Science Foundation should become a billion dollar agency by 1970. "It is little consolation to this subcommittee and its distinguished chairman (Mr E. Q. Daddario) to have foreseen as they did in the 1965 hearings the present predicament of science, and yet not to have been able to implement the major recommendation of (the NAS committee) greatly to expand the National Science Foundation." Dr Weinberg added that in his view the expansion of the foundation was the most important single action to be taken and that if the subcommittee's hearings resulted in nothing else than achieving for the foundation a level of support equivalent to one-tenth of a per cent of the gross national product, or about \$1,000 million a year, he believed that they would have been brilliantly successful.

This reflexion evoked a notable disquisition on the limits of the subcommittee's power and the impotence that has tempered its nevertheless substantial record of achievement. Mr Charles A. Mosher, a Republican member of the subcommittee, observed that although in his opinion the committee had done an extremely important job over the years, "I don't see that it has had much impact on the rest of Congress or on the Congressional decisions, particularly those taken by the Appropriations committees. . . . Too often, it seems to me that the Appropriations committees [which grant the actual monies up to a maximum limit of, but often less than, the sum approved by the Authorization Committees] and the Authorization committees don't have any coordination or even communication. . . . I think it is a sort of mistake that we did as well as we did".

Referring to Dr Weinberg's statement that the subcommittee had heard predictions in 1965 of the present crisis, Mr Mosher continued, "We pointed to it, but who listened? I don't think there is the machinery by which our considerations in this committee are known

by more than a few people. I think the only [sc. effective] devices are really informal devices and the chance of a very vigorous personality. Now Mr Daddario, our chairman, is that type of personality and he has some personal impact. I don't think that the machinery itself, the legislative process itself, is effective or efficient in this regard. I regret to say it. I think it is crucial to the considerations we are discussing".

Mr John W. Davis, presiding over the subcommittee in Mr Daddario's absence, suggested that at least the authorization committees helped by preparing witnesses to make a better showing before the appropriations committees. Dr Weinberg, declining to comment on the relative influence of the two types of Congressional committees, at least agreed on the importance of the charismatic figures such as the late Representative Fogarty who persuaded Congress to keep the money flowing into the National Institutes of Health. Dr Weinberg went on to express his "highest regard for the new director of the National Science Foundation, Dr McElroy: I think he is going to be awfully, awfully good because he has that kind of public presence and dedication . . . I hope he is the one who succeeds in putting across the suggestions that are in here and were in the committee report five years ago".

Like several previous witnesses, Dr Weinberg

CANCER RESEARCH

New Rationale

"SUPPOSE we could develop a vaccine that would immunize us against cancer, say with the same certainty as the Sabin vaccine immunizes against polio. . . . Now an important source (though by no means all) of our concern about environmental pollutants, particularly radioactivity, is prompted by the belief that these agents, even in tiny amounts, are carcinogenic. To prove or disprove their carcinogenic potential at the very low levels at which they appear in the environment is impossible. It seems to me that a more rewarding strategy would be to develop antidotes for the possible untoward medical sequelae of these pollutants. Of these sequelae, cancer is the most important. If cancer could be eliminated by vaccination, our whole attitude toward many environmental problems would change from panic to reason. Thus my plea for heavier support of the National Cancer Institute, and other biomedical research, is entirely consistent with the shift in emphasis toward the environment."—Statement by Dr Alvin Weinberg to the House Subcommittee on Science, Research, and Development.

expressed his distaste for what he saw as the anti-scientism that "is now growing and that could eventually destroy science". Dr Weinberg could only say that this counter culture was "dead wrong" and that its raucous complaints, "which echo in the universities and complicate the relation between the Government and the scientific university, are to be satisfied by more and better science, not by less science".

Equally grave perils were described by another witness before the subcommittee last week, Dr Harrison Shull, Dean of the graduate school of Indiana University. Dr Shull began by saying that the post-war science policy "is now clearly in a state of chaos and perhaps impending collapse" but proceeded to offer some ingenious guidelines for correcting the balance. The annual appropriation cycle is not a suitable way of financing the longer term needs of basic research which, Dr Shull suggested, follow a natural time cycle "of the order of twice the time span of one student's graduate education", or about six to ten years. Congress should provide appropriation mechanisms to ensure such long-term continuity.

Dr Shull criticized the regional distribution of the science fellowships administered by the National Science Foundation. In the financial year that ended

in June 1969, more than half of the 2,500 fellowships in the foundation's gift went to only six institutions. How many institutions should receive so high a level of support? This is the job of a national science policy to decide, but Dr Shull noted that since the 5 million souls of Indiana support three first-rate institutions, the 20 million of California some 11 such bodies, and the 55 million of Britain 27, there is the indication that between 1.5 to 2 million people provide an appropriate tax base and population base to support one first-rate advanced institution. On this reckoning there should be about a hundred such institutions in the United States, well distributed geographically.

Another concern of a national science policy should be manpower planning and Dr Shull believed that the present surplus of PhDs on the job market should have been predicted and forestalled. Dr Shull committed himself to the prediction that there will be an equally severe shortage of PhDs in the hard sciences in five years' time, because the federal government "has reacted so abruptly in changing its support pattern, and there has been so much adverse publicity discouraging young people from entering graduate school and encouraging university departments to limit enrolments artificially".

Literacy for Polluters

"OUR environmental problems are very serious, indeed urgent, but they do not justify either panic or hysteria. The problems are highly complex, and their resolution will require rational, systematic approaches, hard work and patience." These were the words with which President Nixon sent to the Congress this week the first annual report of the Council on Environmental Quality, a document that is to serve as the order of battle for the coming year's campaign against pollution and beyond that to educate the public and polluters into environmental literacy.

The report* represents the first attempt in the United States, and probably in any other country, to consider the whole range of points at which the environment has been altered by man to their mutual detriment. For the benefit of the layman it describes in simple but exact language the various types of pollution that befoul the air and waters and suggests how each should be combated. Many of the fifty or so specific recommendations made in the report have already been embodied in legislative proposals sent to Congress earlier this year which are still awaiting decision.

The Council has not been content to keep its nose to smog, sludge and oil slicks but has lifted its eyes to include the pressures of population on land and on scarce natural resources, and from there to consider the more fundamental question of whether economic growth should be restrained for the sake of conserving the environment. This perhaps is the crucial point at which the ecological fetishists part company from the

rest. The Council, in its own words, has taken "a broad view of the term environment and this broader view reveals many benefits of continued economic growth. Our society needs more goods and services of many kinds—better housing, improved public transportation, more adequate facilities for health and education, and increased pollution control. It is likely that funds for such investments will come not from a cutback in the production of cosmetics, for example, but from an overall increase in national output. Moreover, a reduction in growth would result in a severe blow to the aspirations of the economically disadvantaged, especially minority groups".

This is not to say that the economy can remain unaffected by the attempts to preserve the environment. The Council laconically remarks that in the long run the control of water pollution may possibly require "some changes in the products that people consume . . . and will lead to higher prices for some products". A major theme of the report is that pollution is at present being encouraged by misplaced economic incentives, in that the cost of preventing pollution is borne by the community downstream or downwind of the factory instead of by the manufacturer and his customers. These "external social costs" should be reflected in the price system. Another type of misplaced incentive is the property taxes which lead to bad land use by encouraging local governments to favour industrial developments against houses, which cost more in terms of the schools and hospitals that must accompany them than they yield in property taxes.

The keynote of the Council's report is not despair

*Environmental Quality, the First Annual Report of the Council on Environmental Quality, US Government Printing Office, Washington 20402. \$1.75.

Source: Compiled from data supplied by the Office of Management and Budget, July 1970.

but more what company chairmen invariably describe to stockholders as "cautious optimism"—in other words, a feeling that matters do not necessarily have to progress from bad to worse. What the Council's recommendations boil down to is first and foremost that Congress should not drag its feet with the substantial volume of legislative proposals on the environment that are already before it. These include the setting up of an Environmental Protection Agency to gather under its wings the bits and pieces of environmental control developed by other agencies and the National Oceanic and Atmospheric Administration which would do the same for oceanography and meteorology. Besides the strengthening of the institutional structure for protecting the environment, the Council also makes numerous proposals by which changes in the environment—such as mercury pollution of lakes, for example—will be spotted not too late in the day.

The meat of the report is a description which verges between the scatological and the eschatological of the damage done and the problems to be faced. Only a third of the population of the United States is served by an adequate sewage system and another third is served by no system at all. By 1980 one fifth of the total fresh water run-off of the country will be required for cooling operations by the electric power industry. The refuse collected for each town dweller in the United States has grown from 2.75 lb a day in 1920 to 5 lb a day in 1970, and will reach 8 lb in ten years time. In 1969 Americans threw away about 250 million tons of solid wastes, of which about three-quarters was collected and the rest junked. The collected wastes included 30 million tons of paper, 4 million tons of plastic, 100 million tyres, 30,000 million bottles, and 60,000 million cans. Among the uncollected trash is some 15 per cent of the 9 million cars abandoned each year, and between 1,000 to 2,000 million bottles and cans. There are prospects for recycling some of this litter, if it could be collected; almost the only direct use the Council has come up with is for automobile tyres which, it is suggested, could be used to make artificial reefs for fish breeding along the flat ocean bottom off the Atlantic coast.

The Council's report is more than a month overdue,

though this is hardly surprising since despite the report's appellation as annual, the three members of the Council were not appointed until January this year and have had less than four months in which to survey the state of the nation's environmental health. In these circumstances it is something of an achievement to have produced a report at all, let alone the synoptic and reflective document that has now appeared. The Council is chaired by Mr Russell E. Train, formerly Under Secretary of the Interior and from 1965 to 1969 president of the Conservation Foundation. Of Mr Train's two colleagues, Mr Robert Cahn is on leave from the *Christian Science Monitor*, having won the Pulitzer Prize in 1969 for articles on the national parks, and Dr Gordon J. F. MacDonald is a physicist (one of his interests is the mathematical treatment of the orbital history of the Moon) who has served on several government scientific committees including the President's Scientific Advisory Committee. The Council is served by a professional staff of 15 people, of whom the senior scientist is Dr Lee M. Talbot, previously an ecologist with the Smithsonian Institution.

In the coming weeks the Council's report will be examined before several Congressional committees and as a compendium of facts and recommendations about the environment it will doubtless command considerable attention both within and beyond the borders of the United States. Its lucid prose at least entitles it to a wide readership and if it gains that it will have served one of its principal purposes which is simply to educate.

SST

Booms in the Stratosphere

THE project to build a supersonic transport has run into renewed complaints from the environmentalists. Though the SST may break through this particular sound barrier, the chances of it passing unscathed through the impending Senate hearings on its fat \$290 million budget are probably less bright than at any time in the past.

The SST was one of the topics discussed at the Study of Critical Environmental Problems, a month long conference sponsored by the Massachusetts Institute of Technology and attended by an influential group of scientists from government, industry and the universities. Reporting their conclusions earlier this month, the group expressed concern lest large scale operation of SSTs should begin before the effect of the aircraft on the stratosphere and global climate was better understood. The recommendations of the group were, in brief, that the combustion products of the SST's engines should be better characterized so as to estimate how much water vapour and particulate matter will be injected into the stratosphere by the aircraft, and how these changes are likely to affect weather and climate.

Another attack on the SST has been pressed by the Environmental Defense Fund, which has already feathered its cap by getting the haul road for the Alaska pipeline delayed and requiring the Department of Agriculture to justify its continued use of DDT. The Fund has now taken court action to order the Federal Aviation Administration to set noise and other standards for the SST before granting a certificate of airworthiness.

The resourceful proponents of the SST in the government have met these criticisms by acknowledging the legitimacy of the concern expressed and setting up two councils. Mr William M. Magruder, an aeronautical engineer who since April has headed the SST programme in the Department of Transportation, announced last month that an Environmental Advisory Council would be set up under Dr Myron Tribus, an atmospheric physicist who is Assistant Secretary of Commerce for Science and Technology. This council will study the atmospheric problems raised by the SST, while an equally prestigious Noise Advisory Council, headed by the acoustical engineer Dr Leo Beranek of Bolt, Beranek and Newman Inc. will look into the decibels involved. Mr Magruder also announced that a research programme costing \$27.6 million over three to four years would be carried out by the Naval Research Laboratory and other outside agencies.

Mr Magruder's office is confident that the necessary technological solutions can be found to cope with the SST's contamination of the stratosphere. The high operating temperatures of the General Electric engines being built for the Boeing SST ensure that little hydrocarbon soot is produced. Particles derived from sulphur dioxide are a possible serious source of contamination but it seems more than likely that the sulphur content of the aircraft's fuel can be reduced without significant increases in cost.

The MIT group thought it unlikely that the carbon dioxide introduced into the stratosphere could affect the heat balance, or that the water vapour would reduce the amount of ozone—two possibilities that have been much in the air. But an increase in water vapour of only a few parts per million would amount to a global 10 per cent change which would be expected to increase cloudiness and perhaps to affect climate. The finding that water vapour in the stratosphere above Washington has increased by 50 per cent since 1964 is evidence of how much remains to be understood about this rarefied region.

At \$290 million, the SST's budget for the present financial year is more than twice the size of last year's

appropriation and the plane's neck will offer a tempting target for the Congressional axe. The budget has already been approved by the House of Representatives, although by a much narrower margin than in previous years, and it is unlikely to enjoy plain sailing through the Senate. Even if the American SST should falter at this or a later hurdle, the research programmes now under way are unlikely to be called off as long as the Concorde and the TU 144 threaten to live.

OCEAN DUMPING

Seabed Legislation

from a Correspondent

PLANS for internationalizing the deep seabed and exploiting it for the benefit of mankind as a whole go on apace, but not quite fast enough to prevent the unilateral dumping of dangerous nerve gases in international waters off the Bahamas. This happening would be illegal, it seems, under any of the draft conventions under discussion at Geneva in the current month-long session of the UN Committee on the Peaceful Uses of the Seabed. The discussions intended to lead eventually to an international treaty with the objectives of (1) banning all aggressive military uses such as missile silos; (2) the precise definition of an International Seabed Zone under some kind of international jurisdiction; (3) exploitation of this area for the equal benefit of all nations irrespective of their technological competence and geography (such as coastless countries and those without the resources to bore for minerals a mile or miles below the surface); and (4) protecting the area from harmful environmental interference and for free scientific investigation.

Three countries have tabled draft conventions at this session. By far the most comprehensive is that of the United States Government following President Nixon's directive of May 23 this year. Both France and Britain have produced partial drafts for discussion. The principal differences relate to the definition of the proposed International Zone of the seabed area and to the mode whereby the have-not nations are to obtain revenue from the exploitation undertaken by the haves. The US proposal comes out firmly for making the boundary between "international seabed" and that under some kind of control its 200 metre contour. This, of course, generally corresponds with the edge of the continental shelf. The same draft also proposes an extension of territorial waters out to 12 miles, and a trusteeship role for the seaboard countries over the exploitation of the international region beyond their areas of "national jurisdiction". (Such countries would be entitled to between 30 and 50 per cent of the profit from the exploitation activities, with the rest going to a kind of international kitty for the non-exploiting countries.)

The question of how to apportion the contracts and their proceeds is likely to provoke the most debate. The Soviet Union has already made its objections to any idea that corporations as distinct from sovereign states should be entitled to do the exploiting. Britain has a simpler plan specifying only two classes of seabed zone—territorial and international—and with exploitation licences for international distribution and royalties, collected by the exploiters. Under any agreement, there will have to be provision for the dumping of waste.

Company for Comsat

from our New York Correspondent

THE communications satellite corporation (Comsat) and AT & T will soon face stiff competition from other companies anxious to break their monopoly in domestic long-distance communications. There are not yet any communications satellites covering the United States, and all companies in this field must lease lines from AT & T. Until recently, it was assumed that the Federal Communications Commission would automatically grant Comsat the right to launch domestic satellites. But on March 24 the FCC invited filings from all "financially qualified companies", and last Friday announced that all companies interested in launching a domestic satellite system must apply by August 19.

Western Union is the only company already to have submitted a proposal, but others, including Comsat, are expected to follow in quick succession to meet the August 19 deadline. At this time, the other competitors are expected to include a consortium of the three major broadcasting networks, (NCB, CBS and ABC), the TelePrompter Corporation (a cable television company), General Telephone and Electric Corporation and the Data Transmission Company, a subsidiary of the University Computing Company. All contemplate a working system within two to three years after FCC approval.

There are at present only a limited number of optimum orbital parking spaces in which geosynchronous satellites can efficiently cover the entire United States without interfering with each other, but the number may increase as technology improves and if a broader bandwidth is approved by the FCC. At present, however, the FCC is unlikely to authorize a number of simultaneous systems. A spokesman for the FCC stated last week that no decision will be made until all applications are in. The FCC must then decide, he said, if it will approve only one system, several competing systems or several complementary systems, including both the satellites themselves and the Earth stations which must receive and transmit signals.

Western Union filed a proposal early last week to put up three geosynchronous satellites, two working and one back-up, with a total capacity of 9,000 channels and ten video channels. (A video channel is the equivalent of 200 audio channels.) The system would also include six Earth stations to receive the signals and 31 microwave relay stations to link the ground system throughout the country. The initial cost would be in the range of \$95 million with a running cost of \$10 million, but Western Union estimates that once the entire system was in operation the yearly revenue would be \$28 million.

Most of the other plans under consideration will probably be more complex. Page Communications Engineers in Washington, DC, has just completed a feasibility study for the networks, and has concluded that either a satellite system or a ground microwave system to carry radio and television signals for NBC, CBS, ABC, and the Corporation for Public Broadcasting, the educational network, would cost from \$50 million to \$55 million a year, replacing AT & T facilities for which the networks will be charged approximately \$70 million this year. The satellite system proposed in this

study would comprise three geosynchronous satellites each with the capacity to handle 12 colour television programmes together with television and radio audio and other communications facilities. Approximately 160 Earth stations, 30 capable both of sending and receiving and 130 for receiving only, would be required. An alternative ground microwave system, requiring about 600 towers to cover in excess of 18,000 "system miles", would operate in the common carrier frequencies at a nearly identical annual cost.

While the networks have not yet decided which, if either, system they would go forward with, Alan Cooper, NBC vice-president for planning, stated last week that while the present estimated costs were nearly identical, the satellite system would probably be preferable since its costs are more likely to decrease in the next few years as technology improves.

TelePrompter is another company that in recent months has been studying the possibility of launching its own satellite system. Over a year ago, when it was assumed that Comsat would be putting up the only domestic satellites, the National Cable Television Association proposed that CATV lease six programming channels from Comsat. Comsat was agreeable and felt that 36 Earth stations would be required to link up the six channels to most of the CATV areas. TelePrompter's president, Irving B. Kahn, argued that Comsat's prices were too high and the proposed system too limiting. He later offered to go in with the networks on their consortium when it became apparent that Comsat might not automatically be granted the domestic satellite market. The networks, who still fear the competition of CATV, were unresponsive, leading TelePrompter to commission Hughes Aircraft Company, a major shareholder in TelePrompter, to undertake a feasibility study. The study is investigating both the establishment of ground stations to coincide with CATV headends throughout the country and the launching and operating of an independent satellite. Although not yet complete, Hughes has already concluded that the ground stations themselves could be built for a great deal less than Comsat had originally estimated. TelePrompter's decision to launch its own satellites as well must obviously wait until completion of the study, but there seems little doubt that it will be another strong contender in the satellite sweepstakes.

But what about Comsat itself? At present the corporation is lying low and is seemingly calm about the burgeoning competition, but it is not sitting still. A spokesman for Comsat said last week that it would probably have a filing in within a few weeks. Its past proposals have been similar to that put forward in the Page study; the satellites themselves would be similar to the fourth generation Intelsat satellites being launched early next year with a capacity of 3,000 to 9,000 channels, while past Comsat proposals have contemplated over 100 ground stations.

Where the FCC will go once all these proposals have been filed is still unclear, but now that it has opened the door to companies other than Comsat, it seems unlikely that Comsat will be allowed to continue its exclusive control of the skies.

Introspection in Canada

THE fourth annual report of the Science Council of Canada should help to encourage the introspection and redefining of goals which are now going on in Canada's scientific community. In keeping with the many reports which have been published by the council during its four year lifetime, the report of its activities during the year ending March 31, 1970, is a closely argued plea for a more rational approach to the use of Canada's scientific and technological resources, and the report also points out some of the difficulties of living next to the United States.

The Science Council's fourth year was dominated by federal austerity, from which science and technology did not escape entirely unscathed. Dr O. M. Solandt, the council's chairman, points out, however, that the government was willing to listen to the arguments against cutting back on research expenditure, and made exceptions to its policy of financial restriction in some important areas, for example, the study of water resources and pollution.

The central theme of the report is that economic growth should not be the sole yardstick by which a country's progress should be judged, and that science and technology should not be slaves to a rapidly growing gross national product. Dr Solandt suggests that there is a crucial need for Canada to find reliable indicators other than GNP which will provide a better measure of the country's progress towards achieving national goals. Only when such a yardstick can be found can a set of criteria be drawn up for judging the possible benefits of a new technology. There is also, of course, the evergreen problem of defining national goals.

Part of the process of gearing science and technology to social improvement is the use of the currently fashionable technique of technology assessment, and

Dr Solandt argues that social scientists have a very great part to play in helping to weigh the costs and benefits of new technology. Only if a reliable mechanism for studying the likely long-term implications of a new project can be worked out will it be possible to guard against the misapplication of technology, he argues, and such a mechanism implies an effective teamwork between natural scientists, social scientists and engineers.

In Dr Solandt's view, living next door to the United States can be both a rewarding and a harrowing experience. He points out that the fortunes of Canada are becoming increasingly intertwined with those of the United States, and that Canada tends to import some of the United States' problems into its own cities and universities. There is still time, however, for Canada to take action before it finds itself confronted with some of the problems being faced south of the 49th parallel. One such problem is that the close links between science and the military-industrial complex have resulted in a real antagonism towards science, and this, Dr Solandt argues should be good reason for Canada not to develop an identifiable military-industrial complex of her own.

The chief effect of the proximity of the United States is the comparative ease with which American companies can penetrate Canadian markets and the ease with which Canada finds itself following American policies. "If Canada began to show more independence both in policy and action, as it is now doing in the matter of pollution in Arctic waters," Dr Solandt suggests, "far from causing strained relations between the two countries, in the long run it probably would increase US respect for Canada and Canadians."

As far as immediate problems are concerned, the report suggests that Canada's use of science and technology for development of the Arctic lacks coherence and organization, and that there is an obvious need to define goals for the area and then to mobilize scientific and technological resources to achieve them. There is also the problem of poverty among the Arctic population and the threat of pollution of the Arctic environment. In Canada's cities, the report suggests that there is an urgent need for special aspects of urban research, including transportation. Pollution also gets considerable attention in the report, but unfortunately the only real suggestion given is that more talent and money should be invested in the programme to clean up the rivers and the air.

Finally, Dr Solandt points out that the "major programmes" which were advocated in an earlier report of the Science Council have been very slow in developing. He suggests, however, that some of the blame for this can be laid at the Science Council's own door, because it has been slow to define suitable areas for such programmes, but the declining growth rate of public expenditure on science and technology has also played its part. One programme which has, however, made good progress is Canada's nuclear industry, although there still seems to be some difficulty in involving industry, especially in the design work.

O. M. Solandt, Chairman, Science Council of Canada.

NEWS AND VIEWS

The Universal Initiator

THE capacity to synthesize protein at 37° C in a dilute aqueous environment is virtually half the definition of life. It would therefore be naive to expect the basic pathways of protein synthesis to differ greatly between organisms that are as distantly related as rabbits and bacteria. Protein synthesis is too fundamental a property to have been left to the vagaries of parallel evolution. But on the face of things it would be equally naive not to expect numerous variations on the basic theme to have accumulated since, for example, bacteria and eukaryotes shared a common ancestor. What is so surprising is that these anticipated idiosyncrasies are proving so few and far between.

The story of how bacteria and eukaryotes make protein is proving to be virtually identical even down to the fine print (see pages 672 and 676 of this issue). The initiation of protein synthesis is a case in point. In bacteria the first amino-acid of every polypeptide chain is believed to be methionine, the amino group of which is blocked by formylation. Once the protein has been made, the formyl group is always cleaved and more often than not the methionine residue itself is also clipped from the polypeptide. Bacterial cells contain a unique species of methionine transfer RNA which is not only able to recognize initiation sequence in a messenger RNA but also allows the methionine residue to be formulated, so effecting chain initiation.

But to what extent does this scheme apply to eukaryotic cells? Is methionine the universal initiating amino-acid or is the blocked amino group the crucial characteristic of the initiator? In May, Smith, Marcker and Brown (*Nature*, **226**, 607 and 610; 1970) reported, as Caskey and others before them had done, that eukaryotic cells contain two species of methionine transfer RNA and although eukaryotes lack trans-formylases one of these two methionine tRNAs can be formylated by bacterial enzymes. As Smith and Marcker showed, this species acts as an initiator, incorporating methionine when synthetic messenger RNAs are translated in a cell free system from Ehrlich ascites cells. The other methionine tRNA incorporates methionine internally into the growing polypeptide chain. Moreover, Brown and Smith found that in a cell free system containing all the tRNAs only synthetic messengers with the methionine codon AUG near their beginning are translated.

Synthetic messengers are, however, one thing, natural messengers another. Real proof that methionine is the universal initiator depends on showing that it initiates synthesis of authentic proteins specified by natural messengers. Last year, Sherman and his colleagues reported indirect evidence that this is the case. They found that cytochrome *c* made in certain mutant strains of yeast begins with a methionine residue which is later removed, exposing the normal first amino-acid, threonine. Now Jackson and Hunter (see page 672) and Wigle and Dixon (see page 676) report respectively that rabbit alpha and beta globin chains and protamine in trout testis cells are initiated with methionine.

Jackson and Hunter used sodium fluoride to synchronize at the preinitiation stage a population of ribosomes in reticulocytes. They then removed the sodium fluoride and allowed globin synthesis to initiate but prevented extensive growth of the nascent polypeptides with sparsomycin. By isolating the short polypeptides and analysing their amino-acid composition they have been able to show that methionine initiated their synthesis. They are also able to follow the fate of the initiating methionine and conclude that it is cleaved from the growing globin chain once that is 15 to 20 residues long. Several other groups, whose work has not yet been published, have also by all accounts identified methionine as the initiator of globin synthesis.

Wigle and Dixon's work comes as a great surprise. Trout protamines—arginine-rich basic proteins of low molecular weight—are apparently made on the small polysome comprising two ribosomes and protamine messenger. The advantage of the trout testis material is that it develops synchronously; the synthesis of the protamine occurs at the spermatid stage of development. By labelling a suspension of testis cells at this stage with methionine and extracting the methionine labelled protein, Wigle and Dixon have shown not only that methionine occurs at the N-terminal position in newly synthesized protamines but also that it is never formylated in nascent polypeptides. Moreover, extracts of testis cells contain an enzyme activity which can cleave the bonds between methionine and the second amino-acid, proline. The kinetics of labelling with methionine indicate that the initiating

residue is normally cleaved from the protamine, probably after its synthesis is completed.

Protamines are of course very unusual and specialized proteins. If methionine initiates their synthesis, as well as initiating synthesis of the more mundane globin, the odds must be that methionine is the universal initiator. The sole difference between initiation of protein synthesis in bacteria and eukaryotes boils down to the requirement in bacteria not just for methionine but for methionine with its amino group blocked by formylation. Perhaps the eukaryote ribosome with its increased complexity compared with the bacterial ribosome has during the course of evolution taken over the role of the formyl group and permitted this additional requirement of the initiating amino-acid to be dispensed with.

MARINE BIOLOGY

Young Crabs Described

This larva of the crab *Hemigrapsus crenulatus* is one of eight species described recently, together with a key for identification, by R. G. Wear in the *New Zealand Journal of Marine and Freshwater Research* (4, 3; 1970).

NUCLEIC ACIDS

Ends and Means

from our Molecular Biology Correspondent

IN 1967 Inman demonstrated that some parts of the DNA chain of λ phage undergo thermal melting at lower temperatures than others, and that these labile (presumably because AT-rich) regions could be observed and mapped by electron microscopy. The procedure was to equilibrate the DNA at a chosen temperature within the melting range, prop open the denatured segments with formaldehyde, cool the sample and spread it on a protein monolayer for electron microscopy. The melted regions occur predominantly in one half (arbitrarily designated the right half) of the chain, and form a kind of fingerprint of the DNA.

Since then denaturation maps have been observed for several DNA species, most recently that from a human adenovirus (Doerfler and Kleinschmidt, *J. Mol. Biol.*, **50**, 179; 1970). The molecule, which is

11 μ m long, shows, when 10–25 per cent melted, four well defined zones of denaturation. The value of this approach for a virus of this kind lies in the absence of any genetic characterization. The existence of a unique denaturation map, signifying an invariant distribution of AT-rich segments, is taken to reflect a unique, rather than a permuted, gene sequence.

It seemed from the outset, however, that so finely wrought a technique must find uses beyond the detection of gross variations in composition along the DNA, and this expectation has now been borne out by an accomplished study of the replication of λ DNA by Schnös and Inman (*ibid.*, **51**, 61; 1970). It was established by a group of Japanese workers that shortly after infection of *E. coli* by λ phage some molecules of circular λ DNA appeared, in which two points on the circle were linked by another loop of DNA. It was presumed that the presence of the branch points denoted, in accordance with the currently accepted scheme, that these molecules were in the process of replication. Schnös and Inman addressed themselves to the problem of determining the locus of the replication points. If the circles with loops indeed represent complexes of parent and offspring strands, then the sum of the long, presumed parental, segment between the branch points and the average of the two sides of the loop, or putative offspring segments, should be equal to that of the mature DNA, namely, 17.5 μ m. This turns out indeed to be so. Denaturation maps were then compiled, using alkali, rather than heat, as the denaturing agency, for this was found to give better results. The zones of denaturation, at low overall melting, in mature DNA occur at 8.3–10.6 μ m at 12.7–14.0 μ m and at 16.2–17.1 μ m from the left hand end, and in addition a small zone appears at the left hand terminus. The circular and looped circular species give precisely similar maps as the linear DNA, and the characteristic zones can then be used to index the branch points along the DNA. The loops of offspring DNA could be seen, when they were long enough, to possess identical melting maps to the parental material.

The looped circles that were found corresponded to varying degrees of replication, up to 90 per cent, and fell into three distinct populations: in one the right hand branch point was fixed, irrespective of how far round the circle the other end reached, in another the left hand end was fixed, and in the third and predominant type, neither end was fixed. Where there was a fixed branch point, this was always rooted some 14.3 μ m from the left end (referred to linear DNA), and indeed a plot of the position of the migrating end against the extent of replication was linear, extrapolating to the origin at 14.3 μ m. Similarly, when both branches moved outwards around the circle they did so from this same initiation point, though, as was apparent from the spread of branch positions, not always at exactly the same rate. Evidently then replication occurs most commonly, though not always, on both strands at once, starting from an initiation point 14.3 μ m from the left end. This is known to correspond to the position of the so-called P-gene, and is in a highly GC-rich area. The results seem to dismiss previously propagated notions of replication in one direction only.

It may be noted that after slight thermal denaturation of λ DNA, and rapid cooling, in the absence of formaldehyde (Fukey, Wada and Tomizawa, *ibid.*, 255),

melting is observed only at the extreme right hand end. Evidently, in these circumstances, any internal regions which have melted immediately reanneal when cooled.

SEA FLOOR SPREADING

Non-Axial Symmetries

from our Geomagnetism Correspondent

THE basic premise of the sea floor spreading hypothesis is simply that mantle material rises at mid-oceanic ridges, becomes magnetized in the direction of the ambient geomagnetic field, and moves away laterally and at right angles to the ridge axis to form new ocean floor. There are a few situations in which a more complicated model is required; but, by and large, spreading from a single ridge seems to fit the observations very well.

But into this conceptually simple works, Havemann (*Earth Planet. Sci. Lett.*, **8**, 451; 1970) has thrown a spanner. How big and strong the spanner proves to be only time will tell; but it will no doubt be examined carefully by those who feel that nature cannot be, *a priori*, as simple as sea floor spreading seems to be. For Havemann has noticed that the magnetic anomalies in the South Pacific, the North Pacific and the South Atlantic are symmetrical about the line separating anomalies 25 and 26 as well as about the ridge system. This symmetry seems to lie between anomalies 19 and 32; that is to say, anomalies 25 to 19 are the mirror image of anomalies 26 to 32.

Havemann's explanation of this unexpected discovery is that there may once have been an active ridge between the present anomalies 25 and 26, which is now extinct. In this case the whole sequence of anomalies from 1 to 32 would not have originated by spreading in the same direction. By the same token, the anomalies would not then be in age sequence— anomalies 25 back to 19 would be in inverse sequence. In principle, of course, this suggestion is testable by direct sampling and dating; and will no doubt be tested when enough samples have been collected in the relevant regions.

Meanwhile, is there any evidence that a hiatus in spreading followed by the appearance of a new spreading ridge elsewhere is either possible or likely? There may be. Havemann notes, for example, that the Darwin Rise has subsided and its activity apparently transferred to the East Pacific Rise. A similar displacement may also have taken place, although on a smaller scale, from the Juan de Fuca Ridge which lacks any recent seismic and volcanic activity. Bostrom (*Pacific Geol.*, **1**, 1; 1968) has already suggested that there may be a sub-continental ridge along the coasts of Oregon, Washington and British Columbia.

According to Havemann, the symmetry across anomalies 25 and 26 occurs on one side of the mid-oceanic ridges, but cannot be seen on the other side because the data are unavailable. If it turns out that the symmetry exists separately on both sides, there would, of course, be a problem with the extinct ridge hypothesis. But Havemann is hopeful that such a doublet could be explained satisfactorily. He points out that the East Pacific Rise has a more rift-like topography and higher heat flow on its flanks than on its central line. It may be that an active ridge gradually separates into two ridges which spread apart. Subsequently they may then become extinct followed

by a period of rest and then a return of active spreading to the original central ridge.

Or is it all just an unhappy coincidence?

CRAB NEBULA

Full of Surprises

from a Correspondent

THE Crab Nebula, the remnant of the "guest star" seen by the Chinese in 1054 AD, has had a history of surprises. Hubble first realized the connexion between the ancient supernova and the present nebula when the large expansion motions of about 1,000 km/s⁻¹ were measured. It was the first radio source to be identified by Bolton and Stanley in 1949. Then came evidence of continuing optical activity with light fronts moving outwards from its centre. In 1963 Friedman *et al.* found X-ray emission from the Crab Nebula. The surprises culminated in 1968 in the discovery, by the group at Arecibo, of a pulsar at the centre of the nebula. This identification of neutron matter, the most condensed state of matter in the universe, has excited new interest in the Crab Nebula and its associated pulsar. In the light of this interest the International Astronomical Union sponsored a symposium at Jodrell Bank from August 5 to 7, to make an intensive study of the relationship between the nebula and the pulsar, and to ask how representative they were of other pulsars and supernova remnants.

Dr F. D. Drake (Cornell), reviewing the radio properties of the Crab pulsar, emphasized the variability in the radio pulse in contrast to the optical pulse, where no changes down to a level of several per cent have been observed for about a year. Because the radio pulse can vary by more than a factor of 100, it is possible to investigate the detailed structure of individual strong pulses as well as the mean properties of the pulsar. Drake summarized the data from several observatories, which point to the identification of the Crab pulsar with the compact low frequency radio source at the centre of the nebula, discovered at Cambridge in 1964. The short rotation period (33.1 ms) precluded its identification with conventional optical techniques and, as several speakers pointed out, the pulsed characteristic is largely smeared out at radio frequencies below about 80 MHz, because of multipath propagation effects in the interstellar medium, which broaden the pulse as the fourth power of the wavelength.

In spite of the intensity variability it is possible to obtain extremely accurate radio timing data to complement the optical data with a precision of 1 μ s within a year. (General relativistic effects are 1,500 μ s due to the Earth's motion.) The most intriguing event shown up by the timing observations was the jump in period on September 26, 1969, which corresponded to a decrease in radius of 10 μ m. The gravitational energy released from this minute adjustment in radius was enormous, enough to supply the kinetic energy of one of the wisps found by Scargle to move out from the central star, as reported by Dr V. Trimble (Institute of Theoretical Astronomy, Cambridge).

The interpretation of these timing data was a controversial topic. Dr D. T. Wilkinson (Princeton) interpreted his results as indicating the presence of one or possibly two planetary companions of the pulsar, and he predicted a similar jump to that observed on September 26, 1969, for April this year. But people

who had timing data for this period were not prepared to admit the presence of a jump of similar magnitude, and were inclined to seek an explanation in the processes occurring nearer the surface of the neutron star.

Dr L. Woltjer (Columbia) noted the well established fact that the energy released from the continuing slowdown of the pulsar is comparable with the energy radiated from the nebula, and he emphasized the high efficiency (20–100 per cent) of accelerating electrons and protons to relativistic energies. Although the precise mechanism is not agreed, pulsars can efficiently provide sources of highly relativistic particles in the Galaxy.

Are the Crab Nebula and its associated pulsar unique? Dr D. K. Milne (Radiophysics Division, CSIRO, Sydney) concluded from an extensive survey of about 100 radio supernova remnants that there may be several with the same centrally filled structure as the Crab. These are, however, more evolved, and clearly there is no other source of the same age as the Crab Nebula in the Galaxy. A similar conclusion was reached for the Crab pulsar—none of the same age have been detected, but several have similar pulse shape and polarization characteristics.

Many problems remain. What, for example, is the role of general relativity in the high densities of neutron stars? Why do all the 55 pulsars known have a pulse width close to 3 per cent of their period? Professor F. G. Smith (Jodrell Bank) reminded delegates that although many pulse characteristics could be conveniently explained in terms of the generally accepted oblique rotating magnetic field model, there were difficulties in explaining the high degree of circular polarization at the edge of the pulses. He suggested that this is some maser amplification process operative at radio wavelengths.

SUPERNOVAE

X-rays from Cygnus Loop

from our Observatories Correspondent

THE detection of soft X-rays from a source (Cygnus X-5) which is thought to be the Cygnus Loop has been reported recently in *Astrophysical Journal Letters* (161, L45; 1970). The discovery was made by a team from the Lawrence Radiation Laboratory of the University of California, R. Grader, R. Hill, and J. Stoering, who used rocket-borne equipment.

The Cygnus Loop is the classical example of an old supernova remnant. It is composed of very fine filaments of emitting nebulosity which comprise two large diametrically opposed segments of a circle, about a degree across in the sky. (Portions of these filamentary structures, which by and large are tangential to the circle, are frequently used as illustrations in popular books on astronomy under such beguiling names as the "veil nebula" or the "network nebula".) In 1946 J. H. Oort suggested that the filaments form an expanding shell which resulted from the explosion of a supernova some 50,000 years ago and that the emitting gas is excited by collision with the ambient interstellar medium. E. Hubble had earlier shown that the fine filaments are indeed moving outwards at a measurable rate, about 3 seconds of arc per century. In 1958 R. Minkowski showed from spectroscopic measurements that the radial expansion velocity of the shell is about 100 km s^{-1} . The luminous filaments seem to be shock fronts moving at about this speed into the

Cygnus Loop

undisturbed interstellar gas. The gas immediately behind a shock front moving at 100 km s^{-1} would be ionized and heated to a temperature of a few hundred thousand degrees. Minkowski's use of both the radial and transverse components of the motion enabled him to estimate that the shell is at a distance of about 770 parsecs and that its diameter is about 40 parsecs. A sphere of this diameter in the galactic disk would be expected to contain about 2,000 solar masses of interstellar neutral hydrogen which in this case has been swept up by the shock front created in the initial supernova explosion.

The LRL group detected X-rays from the Cygnus Loop in the energy range 0.1 to 2 keV with a peak at 0.2 keV. This fall in emission below 0.2 keV can plausibly be attributed to absorption by interstellar gas. The experimenters are not certain of the origin of the emission. The observed X-ray spectrum above 0.2 keV can be fitted either by a power law of the kind produced by synchrotron radiation or by an exponential which would be produced by thermal bremsstrahlung from a hot gas at about 4 million K. A thermal origin seems to be the more likely hypothesis, although the required temperature seems a little high in view of the known expansion velocity of the shell. Nonthermal radio emission is observed from the Cygnus Loop. According to H. van der Laan it is synchrotron radiation produced by galactic cosmic ray electrons as they traverse the compressed interstellar magnetic field behind the shock front.

Whichever theory turns out to be right, it seems that X-ray observations will give important data on the evolution of supernova remnants from relatively young objects such as the Crab Nebula to objects as old as the Cygnus Loop.

ATOMIC PHYSICS

More Uses for Lasers

from a Correspondent

ADVANCES in experimental techniques reported at the international conference on atomic physics, held in

Oxford from July 21 to 24, included improvements in methods of trapping free ions for sufficiently long times (milliseconds) to permit very narrow cyclotron resonance linewidths to be obtained. These developments, which should lead to considerable improvements in precision of magnetic moment ratio determination, and collision frequency measurements, were reported by Professor M. Bloom (University of British Columbia) and Professor A. Rich (University of Michigan). Observations of weak absorption lines in the solar spectrum, and the advances in spectrophotometric techniques which made such observations possible were described by Professor D. E. Blackwell (University of Oxford). Improvements in spectroscopic techniques, including such refinements as interferometric measurement of reflector displacement using super-radiant laser sources in Fourier transform spectroscopy, were further detailed by Dr P. Boucharcine (Orsay).

A new technique for producing high densities of spin polarized atoms, ions and electrons was announced by Dr L. D. Scheerer (Texas Instruments Inc.). The helium triplet metastables in a flowing helium afterglow acquire a net polarization of about 30 per cent by absorption of circularly polarized light from lamps irradiating the afterglow stream. As a result of Penning reactions and charge transfer collisions, the polarization can be transferred to excited and ground state ions of gases or vapours titrated into the gas stream. Radiofrequency resonance measurements have thus been made on various ions, many of which were previously considered inaccessible to optical pumping.

Professor S. Bashkin (University of Arizona) described recent results of oscillator strength measurements and assignments of spectral lines from multiple ionized species observed for the first time in laboratory sources, obtained using the beam-foil technique.

Professor A. Javan (Massachusetts Institute of Technology), describing his work on beating laser frequencies in the infrared with harmonics of electronically generated microwave signals, announced that all the individual steps in the chain of procedures which would allow determination of the frequency of a visible gas laser in terms of the caesium clock standard had been demonstrated. Vital to the establishment of a bridge between microwaves and infrared was the development of a mixing diode which uses a hair-like antenna wire of a few microns diameter, tapering at the rectifying contact to a tip of radius 500 Å. Dr H. Walther (Joint Institute for Laboratory Astrophysics, Boulder, Colorado) announced the development of a dye laser with a narrow frequency band output. The possibility of concentrating the laser's normally broad band output into a frequency range no wider than a few hundred MHz, while retaining the ability to tune the output across most of the visible spectrum, was realized by combining a grating end reflector with a Lyot filter inside the cavity. Comparisons of evidence available from studies of isotope effects in optical spectroscopy with predictions of nuclear models and the theory of isotope effects in muonic X-ray spectra were reviewed by Drs D. N. Stacey (Oxford) and R. C. Barrett (Surrey).

Professor E. W. Otten (Heidelberg) described work alignment of extremely small (less than 10^6 atoms) samples of radioactive nuclei, produced by bombardment of rare-gas atoms and polarized in spin-exchange collisions with optically pumped rubidium. Asymmetry

of the beta-decay provided the diagnostic tool for detection of radiofrequency resonance.

In the final session Professor J. G. King (MIT) described an interesting and novel technique for detecting the quantized vortex structure of superfluid helium through the interaction with an atomic beam.

CONTINENTAL DRIFT

When did Gondwanaland Split?

from our Geomagnetism Correspondent

As far as the continents around the Atlantic Ocean are concerned, one of the most authoritative and widely accepted pre-continental drift configurations is the purely geometrical fit based on a least squares analysis of continental margins at the 500-fathom contour (Bullard *et al.*, *Phil. Trans. Roy. Soc., A*, **258**, 41; 1965). Recently two attempts have been made to test it using palaeomagnetic evidence. The first utilized all relevant Permian and Carboniferous pole positions available to 1964, irrespective of whether or not the rocks concerned had been magnetically cleaned. The results of this test were inconclusive, probably because of the inclusion of the less reliable data. A second attempt was made in 1968, using only data from rocks which had been adequately cleaned. And again the results were inconclusive, simply because there were too few reliable data.

Larson and LaFountain (*Earth Planet. Sci. Lett.*, **8**, 341; 1970) have made a third attempt to test the Bullard fit palaeomagnetically because they feel that there is now enough good data available to make it worthwhile. Their conclusion, based on an analysis of Permian and Carboniferous pole positions, is that the Bullard fit is valid within the limits of the technique. But, what is perhaps more important, by extending the polar analysis to the Triassic and Cretaceous, Larson and LaFountain have determined, with greater precision than before, the time at which the continents began to drift apart.

The technique they have adopted is to hold North America stationary and rotate the other continents into the relative positions indicated by the Bullard fit. When this is done, Carboniferous poles from Eurasia and North America, which were widely separated before the rotation, move to near coincidence. Permian poles from North America, Eurasia and Africa show the same behaviour. From this it is a fair inference that during the Carboniferous and Permian, Europe, North America and Africa were contiguous or almost so. The situation with regard to the other major continent, South America, is less certain; but in so far as the few available poles move towards the common pole when rotated, the same conclusion can justifiably be drawn.

In the Triassic the polar coincidences after rotation are not quite so good, which would seem to indicate that this was when the continents began to split. This is confirmed by the behaviour of the Cretaceous poles. Rotation of the African poles to the Bullard fit produces first a convergence and then an increased scatter. This would be expected if the rocks concerned had been magnetized since drift began. Furthermore, the closest coincidence of North American and African Cretaceous poles occurs about halfway

along the rotation path. This can only mean that by the Cretaceous (80–100 million years) the South Atlantic had already opened by about 50 per cent, having begun to open during the Triassic about 200 million years ago. Rotation of the Eurasian poles, on the other hand, produced divergence right from the start. By about 100 million years ago, therefore, the North Atlantic (above 40° N) must have been about as wide as it is now.

It must be said, however, that the time of break-up of the continents (200 million years) determined in this way does not agree with that deduced from Atlantic sea floor spreading (less than 100 million years). Which, then, if either, is correct? The discrepancy could arise from incorrect palaeomagnetic pole positions, wrong sea floor spreading rates, or possibly a situation in which the Atlantic sea floor is spreading beneath the continental edges. There is no evidence for the last of these—there are, for example, no earthquake zones as there are near the descending Pacific Ocean floor—and it is impossible to evaluate properly the possibility of incorrect pole positions. But, as Larson and LaFountain point out, the sea floor spreading determination is the most likely to be incorrect. Times of continental break-up determined from sea floor spreading are based on linear extrapolations of spreading rates during the past five million years. Only a brave man or a fool would deny the strong possibility of error in an extrapolation from 5 million to 100 or 200 million years. The best estimate for the time of break-up of Gondwanaland is thus 200 million years ago.

MATERIALS

Explosive Preparations

from a Correspondent

DIVERSE aspects of materials forming processes were the theme of a conference held at Swansea by the Materials Science Club on July 23 and 24. Setting the scene, Dr B. Lengyel (Imperial College, London) discussed engineering limitations to forming processes, such as the vessel size in hydrostatic extrusion. For high speed metal forming processes, it is important to relate temperature, strain, strain rate and pressure effects, for there are certain advantages in operating at room temperature and high strain rate. Temperature effects introduced by converting plastic work to heat must be considered, however, particularly with regard to heating of the die and interface with a subsequent change in the interfacial lubrication conditions. Pressure increases the strain at fracture and has great potential for extrusion of brittle materials. Furthermore, because voids can be induced to heal, effects can be achieved similar to those obtained in hot working.

Discussing the technique of high velocity forming (HVF), Dr A. J. Organ (University of Birmingham) identified three process categories: stroke restricted, power restricted, and work restricted. In pneumatic mechanical forming practice, a high gas pressure is applied to a ram to give it a high velocity (say between 10 and 60 feet per second), and on impact the kinetic energy is equivalent to the plastic deformation of the workpiece. When HVF was applied to cropping, it

was pointed out, there was usually no wastage of materials and the process was cheaper than sawing.

In explosive forming, much greater velocities are used (10^3 – 10^4 feet per second), and because of the nature of the operation it is usually done out of doors. Mr E. Amini described how this technique has been refined at the University of Birmingham using fairly simple equipment to enable 2 foot diameter disks to be explosively formed indoors using moderately low explosive charges.

Two major recent developments have revolutionized the use and fabrication of glass. Mr H. Charnock (Pilkington Ltd), who reviewed the float glass process, emphasized particularly the importance of familiar surface chemistry equations for predicting the glass plate thickness, and suggested engineering solutions to the problem of producing glass of various thicknesses. In the second case, although the uses for fibre optics are still developing, Mr C. I. Western (Rank Kershaw) said that significant advances have been made in the manufacturing processes. There are clear distinctions in the techniques for producing randomly oriented fibre bundles for light transmission and those for producing coherent bundles of two million individual fibres for picture transmission.

Reviewing recent advances in the fabrication of ceramics, Dr D. I. Matkin (Atomic Energy Research Establishment, Harwell) discussed the developing technique of incorporating a certain amount of organic plastic into the ceramic powder. The result may be formed by extrusion or injection moulding and the plastic subsequently burnt out in part of the firing process. If silicon resin is used, the technique can be adjusted so that the final product contains silica. Continuous hot pressing represents a break-through in ceramic fabrications. If two plungers are used, and the top one can be removed to introduce more powder after each compaction, together with a specially designed die, the material pressed eventually becomes the bottom plunger enabling long ceramic rods of simple shape to be formed.

To form engineering components successfully in plastic requires not only a simple technique to keep costs at a minimum, if the advantage of a low-priced material is not to be lost, but also the expertise of the tool designer. Dr M. Abrahams (GKN Ltd) described a technique for hydraulic pressing of plastic components from injection moulded billets. In the final product the tensile properties are non-uniform in the radial direction; the technique is considered to be complementary to the injection moulding of components, but whether or not the change in properties produced is beneficial in the long term remains to be seen. Mr I. T. Barrie (ICI Ltd, Plastics Division) discussed how conventional melt processing of plastics is being modified for a more discerning market. For example, the production of the integral plastic hinge, as an accelerator pedal, is an interesting example of the way the melt flow behaviour into the mould requires careful study to optimize the conditions to give satisfactory properties. Again, injection moulding processes must be better understood if larger components are to be formed without the need for scaling the equipment consistent with present operational experience. A good example is the production of car bonnets, which has been achieved using a piston approach to the mould design to produce these large components at moderately low operating pressures.

Phytochrome and Photomorphogenesis in Plants

by

HARRY SMITH

Botany Department,
University of Manchester

Much of the information available about the behaviour of phytochrome in plants can be brought together into a model involving association of the pigment with membranes.

MANY aspects of morphogenesis in higher plants are regulated by light. Typical examples include the photo-periodic control of flowering and bud dormancy, the regulation of leaf and stem expansion, the stimulation or inhibition of seed germination and the biosynthesis of various pigments (reviews in ref. 1). During the two decades before 1960, intensive investigations of the action spectra and energy requirements of various photoresponses, led principally by Drs H. A. Borthwick and S. B. Hendricks at the US Department of Agriculture Research Station at Beltsville, culminated in an elegant and intellectually satisfying unification.

It had been found that many photomorphogenetic phenomena had very low energy requirements and were reversibly potentiated and negated by short periods of red light ($\lambda_{\text{max}} = 660 \text{ nm}$) and far-red light ($\lambda_{\text{max}} = 730 \text{ nm}$) respectively, the nature of the ultimate response being determined by the final irradiation treatment². On the basis of this evidence, the Beltsville group predicted that the photoreceptor (P) existed in two photoconvertible forms: P_R , absorbing maximally at 660 nm, and P_{FR} , absorbing at 730 nm, and that the form produced by red irradiation was responsible for the subsequent developmental events. Thus:

In 1959, this prediction was decisively borne out by the direct demonstration of the expected absorbancy changes in living tissues, and by the successful extraction of the photoreversible pigment as a chromophoric protein³. At this stage, the role of phytochrome, as the pigment was named, seemed reasonably clear and uncomplicated; it only remained to discover the nature of the initial primary reaction catalysed by the presumed enzyme, P_{FR} . This concept of phytochrome action was truly germinal, and since that time investigations into the nature of phytochrome action have increased enormously in quantity, ingenuity and complexity. Unfortunately, although this work has substantially increased knowledge of phytochrome, it has also, perhaps inevitably, considerably confused the overall picture. Hypotheses of the action of phytochrome in specific developmental phenomena have proliferated and the unity of the early ideas has been largely lost. It is my purpose here to attempt to draw together these divergent trends and to clarify as far as possible the general picture for the non-specialist reader.

Phytochrome a Protein

Phytochrome has been isolated and purified by several groups and shown to be a protein, probably existing in monomeric and polymeric forms, the monomer with a molecular weight of about 42,000⁴. The chromophore is a linear tetrapyrrole of the bilatriene configuration⁵, but the complete structures of the P_R and P_{FR} forms are not yet fully worked out. There is evidence for the existence of multiple chromophore forms in at least one plant

species⁶. Flash spectroscopy investigations of the *in vitro* photoconversions of P_R to P_{FR} and *vice versa* have shown the existence of several intermediates and partial reactions with differing rate constants⁷. Evidence has also been adduced for the existence of "leuco" or colourless forms of both P_R and P_{FR} ⁸ and of long lived intermediates⁹. Thus the photoconversions are chemically quite complex. They are further complicated by associated changes in the tertiary structure of the protein moiety of the molecule¹⁰. The binding of the chromophore to the protein is very strong, and isolated chromophore material does not have the capacity for photoreversible conversions⁶. The conversions, therefore, are properties of the whole, intact molecule. Non-photochemical conversions also occur in isolated phytochrome, in particular a relatively slow reversion of P_{FR} to P_R , and a conversion of P_{FR} to an unknown, photochemically inactive, derivative¹¹.

The absorption spectra of the two forms (Fig. 1) have overlapping absorption bands which render total photochemical conversion impossible. Thus 660 nm light produces an equilibrium of approximately 80 per cent P_{FR} and 20 per cent P_R , while the proportion of P_{FR} present under 730 nm irradiation is usually less than 3 per cent of total P ¹². Similar considerations apply to photochemical conversions *in vivo*. Non-photochemical conversions also occur *in vivo* but seem to be kinetically different from those of purified phytochrome¹³. The dark reversion of P_{FR} to P_R , originally thought to be widespread and to be implicated in the time-measuring mechanism in photoperiodism, is now considered to be restricted to only certain dicotyledonous tissues, including etiolated pea and bean shoots¹³, and cauliflower head tissue¹². Thermochemical transformation of P_{FR} to a photochemically inactive form (a process known as "decay" or "destruction") is widespread *in vivo* but, in contrast to the similar *in vitro* conversion, is dependent on metabolic activity¹⁴. The decay process is restricted to P_{FR} and is in most cases a first order reaction, the total loss of P being dependent on the equilibrium proportions of P_R and P_{FR} in the particular conditions. Thus decay is rapid under

Fig. 1. The *in vitro* absorption spectra of the P_R and P_{FR} forms of phytochrome. (By permission of Dr K. M. Hartmann, ref. 37.)

red irradiation, which maintains a high proportion of P_{FR} , and is slow under far-red irradiation, which maintains a low proportion of P_{FR} . In some etiolated tissues, an apparent resynthesis of P_R can be observed in darkness, occurring only when the concentration of total P has been reduced below a critical level¹⁵. It is important to remember that all *in vivo* determinations of phytochrome are dependent on the changes in absorption at 660 and 730 nm as measured, usually, by a dual-wavelength difference photometer specifically designed for dense, light scattering samples¹⁶. Thus, "losses" and "gains" of phytochrome refer to the disappearance or appearance of spectral photoreversibility and do not necessarily involve major changes in the phytochrome molecule.

Considerable effort has been expended on attempts to determine the location of phytochrome within the plant as a whole, and within the cell. It is now generally agreed that phytochrome is concentrated in the meristematic and elongating regions of etiolated seedlings, whether it is measured by *in vivo* photometry or by extraction¹⁷. Seedlings grown in the light, however, contain such low concentrations of phytochrome that it is not possible to determine accurately the regions of highest concentration. The problem of cellular location is even more obtuse, for the solubility of the pigment is markedly dependent on pH. Thus, when alkaline buffers are used, phytochrome appears predominantly in the final supernatant on differential centrifugation, while slightly acidic buffers may cause its spurious precipitation onto organelles. Evidence for the possible localization of phytochrome in the nucleus or nuclear membrane of etiolated *Avena* cells comes from Galston's¹⁸ observation of photoreversible spectral changes using a microspectrophotometer. The observed spectral changes are unexpectedly large for such a small path length, however.

The most convincing evidence of the cellular location, however, is the demonstration by Haupt¹⁹ of the dichroic orientation of the pigment molecules in the plasmalemma of *Mougeotia*, a filamentous alga with a flat, plate-like chloroplast which rotates within the cell in response to the photoactivation of phytochrome. Haupt²⁰ has also shown, using microbeams of polarized red and far-red light, that the axis of orientation of the chromophores is parallel to the plasmalemma surface in the P_R form, but is changed to an orientation at 90° to the surface of the plasmalemma when photoconverted to P_{FR} . The localization of phytochrome in the plasmalemma of *Mougeotia* does not, of course, prove that it is similarly located in the other organisms, but it seems reasonable at present to conclude that phytochrome is usually a constituent of certain cellular membranes. This conclusion is supported by the physiological evidence described later.

Several workers have used the *in vivo* photometric method in attempts to determine the extent of correlation between the proportion of phytochrome converted by a particular light treatment and the final morphogenetic responses. In most etiolated plants, the correlation is very good, the final response being proportional to the logarithm of the percentage P_{FR} set up by a single irradiation^{21,22}. In plants grown in the light, however, it is not possible to carry out such experiments, and even in some etiolated tissues the correlations are non-existent. Two of the most striking examples have been dignified by the name "paradox". In the *Zea mays* paradox²³, light energies so low that they do not establish photometrically detectable amounts of P_{FR} will saturate the decrease in phototropic sensitivity which is mediated by red light.

Even more mystifying is the fact that this effect can be reversed by energies of far-red irradiation that are known to establish a higher proportion of P_{FR} than the low energies of red light used. In the *Pisum* paradox²¹, epicotyl segments, cut from etiolated seedlings the growth of which has been inhibited by brief irradiation with red light 8 h previously, are stimulated in their growth by far-red light even though photometric assays show that all P_{FR} established by the prior red light has disappeared (through dark reversion and decay). The phenomenon of far-red reversibility in the absence of detectable P_{FR} is widespread and, together with the *Zea* paradox, has led to the postulation of "bulk" and "active" forms of phytochrome, the bulk form being photometrically detectable in etiolated tissues but, at least in some cases, physiologically inactive. Another difficulty for the simple correlation of the ratio of P_{FR} to P with physiological effect comes from the report of a threshold of P_{FR} for repression of lipoxygenase synthesis in mustard seedlings²⁴. The absence of a graded effect suggests that P_{FR} functions through an all or nothing control mechanism of high precision.

Hormones and Membranes

Early work on the energy-response relationships of several photoresponses suggested that P_{FR} was the active form and that its action was relatively slow and cumulative. It now seems likely that the primary action of phytochrome can occur very soon after photoconversion, although the intervening processes between this primary reaction and the developmental events may take hours or days. The most striking example of rapid action is the phytochrome regulation of the closing of the leaflets of *Mimosa pudica* and related legumes, in which the photoconversion and the response are separated by less than 5 min²⁵. Other rapid responses are also known. The germination of 'Grand Rapids' lettuce seeds can be promoted by red light or by gibberellin. In the presence of sub-threshold levels of gibberellin, the red light stimulation of germination is not reversible by far-red light, even when given immediately after the red irradiation²⁶. This suggests that a product of P_{FR} action interacts immediately with gibberellin. Rapid action of phytochrome has also been found in the unrolling of cereal leaves²⁷ and in the photoperiodic control of flowering²⁸. It is thus clear that hypotheses of the mechanism of action of phytochrome must take into account the rapid action evident in these responses. In 1967 Hendricks and Borthwick²⁹ made yet another significant contribution to the subject by postulating that phytochrome is a controlling factor in membrane permeability, and that the rapid and slow responses both stem from this primary membrane effect. The basis of this hypothesis is the regulation of *Mimosa* pinnule movements which are thought to be caused by massive changes in osmotic potential in the pulvinal cells, brought about by changes in membrane permeability. A more dramatic response which is also thought to involve changes in membrane properties is the red/far-red photoreversible adherence of barley root tips to a glass surface³⁰. A rapid change in the electrostatic properties of the root surface is clearly involved here and, in fact, red/far-red changes in electrical potential have been reported³¹. Thus, although it cannot yet be regarded as conclusive, evidence is building up for the localization of phytochrome in certain critical membranes and for its having a function in the regulation of membrane properties.

Phytochrome and Gene Expression

The membrane hypothesis has tended to supersede the slightly older hypothesis, proposed by Professor Hans Mohr of the University of Freiburg, that phytochrome interacts specifically with the genome to regulate gene expression and thus to determine long term morphogenetic events through the induction and repression of specific enzymes³². That such a hypothesis cannot account for the rapid effects of gibberellin on lettuce seed germination which I have described makes it seem unlikely that P_{FR} interacts directly with the genome. On the other hand, many long term phenomena controlled by phytochrome can be inhibited by actinomycin D and inhibitors of protein synthesis in a manner which supports the involvement of enzyme synthesis³³. Furthermore, direct observation of phytochrome has been observed, a particularly good example being phenylalanine ammonia-lyase, a critical regulatory enzyme in flavonoid biosynthesis³⁴. The two hypotheses, of course, are not mutually exclusive, and may operate independently or even sequentially. For example, the primary change in membrane properties may lead to the transfer of an important metabolite, perhaps a hormone, from one membrane-bound compartment to another in which it can interact with other substances (for example, gibberellins) and from which it can go on to regulate, in some way, enzyme synthesis and the ultimate morphogenetic phenomena.

At this stage it must be pointed out that most investigations of the role of phytochrome have been concerned solely with plants grown in the dark. Photomorphogenetic phenomena, however, are by no means restricted to etiolated plants, and it is of importance to consider phytochrome in the context of the rather more "natural" light-grown state. As I have said, phytochrome has been extracted from some light-grown plants, although many plants, even some of those exhibiting definite red/far-red photoreversibility of flowering, yielded no detectable phytochrome³⁵. This is presumably because of the loss of spectral photoreversibility of phytochrome through the process of decay, and poses two complementary problems for the physiologist. On the one hand, what is the function of the relatively very large amounts of phytochrome in dark-grown tissues; and on the other hand, how can photomorphogenetic phenomena be regulated in a typical phytochrome fashion in light-grown plants that contain no detectable phytochrome?

Many photomorphogenetic phenomena are known which require prolonged irradiation with sources of relatively high energy. Such processes, which have been grouped under the collective term "the high energy reaction", typically do not show red/far-red photoreversibility and have action maxima above 700 nm, although some have other action maxima in the blue regions of the spectrum³⁶. Hartmann³⁷ has constructed a hypothesis which satisfactorily accounts for the >700 nm action maxima on the basis of phytochrome (the activity in the blue region is thought to be due to other photoreceptors; for example, carotenoids or flavins). In Hartmann's view, the far-red wavelengths establish an equilibrium between P_R and P_{FR} in which P_{FR} is in low concentration; thus the rate of disappearance of total P due to decay is low. Under continuous illumination with wavelengths which maintain a high proportion of P in the P_{FR} form (for example, between 600 and 680 nm) the rate of loss of total P is much greater. Maximum developmental effect is obtained in conditions in which low concentrations of P_{FR} are

Fig. 2. Hartmann's hypothesis for the explanation of the high energy reaction on the basis of phytochrome³⁷.

maintained for maximum periods, that is, under far-red illumination. The hypothesis, which is represented in Fig. 2, has been tested successfully in several plant tissues utilizing mixed sources of red and far-red irradiation. In extension growth of lettuce hypocotyl³⁸, for example, maximum inhibition is obtained under continuous irradiation with a sharp maximum at 716 nm, under which approximately 3 per cent of total P is present as P_{FR} . If lettuce hypocotyls are irradiated with a standard energy of 768 nm and simultaneously with varying energies of 658 nm (neither of which wavelengths have any effect independently), a level of 658 nm energy is reached which gives strong inhibition. Above this level, the inhibitory effect is gradually diminished. Calculation of P_{FR} levels shows that inhibition is obtained with mixtures of 658 and 768 nm energies which maintain approximately 3 per cent of total P as P_{FR} . Other similar tests also support the Hartmann hypothesis as far as the involvement of phytochrome is concerned, although it is difficult to explain the observed intensity dependence of many high energy reactions on the basis of this hypothesis. Furthermore, the hypothesis has been criticized³⁹ for its assumption that all, or at least a constant proportion, of the phytochrome present in a tissue is active and that decay as seen in etiolated tissues is of physiological importance. Some high energy responses—namely, the maintenance of pinnules of *Mimosa* in the open position, and the extension growth of stems of *Hyoscyamus niger*, *Beta vulgaris*, and *Spinacea oleracea*—have been shown⁴⁰ to have sharp action maxima at 720 nm even when the ratio of P_{FR} to P_R is maintained at a high value by supplementary irradiation with red light. Borthwick *et al.*⁴⁰ have used these examples to extend and complicate the Hartmann hypothesis by suggesting that P_{FRX} (Fig. 2) is dissociated by light with an action maximum at 720 nm but with very little effect in the red regions. This assumption would explain the exceptions to Hartmann's hypothesis, but is not supported yet by any direct evidence about the nature of P_{FRX} .

To sum up, phytochrome is probably located in certain critical membranes, where it is likely to be orientated in a specific dichroic manner. Photoconversion leads to a change in the dichroic orientation of the chromophore and to a change in the tertiary structure of the molecule. P_{FR} is subject to a transformation to a photochemically inactive, but otherwise unknown, form, while P_R may be resynthesized in response to a fall in the levels of total phytochrome. There is evidence that P_R and P_{FR} exist in two forms, a bulk, or "nonsense", form that is photochemically active but physiologically inactive in etiolated tissues, and a minor component that is physiologically active probably in both etiolated plants and those grown in the light. Certain phenomena regulated by phytochrome illustrate a very rapid action of the pigment,

while others demand a series of partial reactions possibly involving the synthesis of enzymes. The far-red sensitive high energy reactions seem in most cases to be explainable in terms of phytochrome. In spite of these advances, many problems still hinder understanding of phytochrome action. Basic questions are involved in the explanation of the specificity of phytochrome responses and their amplification. More challenging problems, perhaps, lie in the nature of phytochrome in plants grown in the light, the role of the decay process, and the explanation of the intensity dependence of the high energy reaction.

Model for Action

Some of these problems can be accounted for satisfactorily by the simple but speculative model presented in Fig. 3. This model is an attempt to rationalize the existing information on phytochrome action and to provide, in particular, a basis for the rapid action and intensity dependence. Phytochrome is thought to exist as orientated molecular arrays in certain critical membranes and its primary action is to transfer an important metabolite (X) from one side of the membrane to the other. This transfer could be driven directly by the conformational changes associated with the photoconversion of P_R to P_{FR} . This assumption would provide a simple explanation for the intensity dependence of the high energy reaction—the higher the intensity of irradiation with wavelengths absorbed by both P_R and P_{FR} , the greater the rate of cycling between P_R and P_{FR} . As long as the mechanisms for the utilization of X on one side of the membrane and its availability on the other side are not rate limiting, the overall rate of reaction will be determined by the rate of cycling and thus by the light intensity. It is not necessary to implicate phytochrome decay to account for the action spectrum of the prolonged-irradiation, high-energy reaction. Because P_R or one of its early photoproducts is assumed to bind to X^1 , maximum rate of transfer might be expected to occur at wavelengths which maintain a high proportion of P_R but still allow sufficient absorption by both P_R and P_{FR} for cycling to occur. For short term irradiations of tissues fully grown in the dark, on the other hand, maximum effect would occur with wavelengths which convert the maximum amount of P_R to P_{FR} . Long term reversibility of events potentiated by a single red irradiation may be due to the utilization of X being limited by the availability of the metabolite or metabolites with which it interacts (A in Fig. 3). On the other hand, the rapid action effects I have described could be due to the immed-

iate interaction of a small part of X^0 with the limited amount of A available, thus producing a small, non-photo-reversible developmental response.

In common with other hypotheses of phytochrome action, this model does not account for the specificity of response, which must reside in the particular state of the genetic control systems in the target cells. Amplification of the response can be ascribed to the synthesis or activation of enzymes caused by the interactions of X once released from its sequestration.

The salient feature of this model is the suggestion that the function of phytochrome is to act as a specific permease for an important metabolite, perhaps a hormone, and that this action is driven directly by the photoconversions. I should like to stress that this model is completely speculative and is not supported by any direct evidence except in so far as it accounts for several of the problems of phytochrome action. The only possible justification for presenting it here is that it may stimulate investigations designed to determine its validity—or otherwise. I hope this will be the case.

I thank Professor P. F. Wareing and Professor M. B. Wilkins for commenting on the manuscript of this article.

Fig. 3. The speculative model of phytochrome action proposed in the text. P_R^+ and P_{FR}^+ are immediate photoproducts of P_R and P_{FR} ; X^1 represents the pool of X inside the membrane-bound compartment whilst X^0 is the pool of X outside the membrane; A represents one or more metabolites, outside the membrane, with which X interacts, thus initiating the sequences of reactions leading to the morphogenetic processes; W represents the precursors of X . The scheme should not be taken to indicate that phytochrome molecules move within the membrane, rather that the binding sites for X are anisotropic, leading to binding of X on one side of the membrane and its release on the other side. See text for details.

Citation Indexing for Studying Science

by

E. GARFIELD

Institute for Scientific Information,
Philadelphia, Pennsylvania 19106

By revealing who has really influenced the course of science the *Science Citation Index* seems to be a valuable sociometric tool for historians and sociologists.

By writing the *Double Helix*¹, Watson laid to rest the absurd notion that scientists have less desire for reputational immortality than other humans. That this belief could have existed at all is only a sign that the efforts of scientists to achieve fame and fortune are necessarily less obvious than those of athletes and politicians. We are thus confronted by a situation wherein those scientists who deserve (and want) recognition cannot always be easily identified, even by their peers. It seems likely, then, that social scientists—whose role is to tell it like it is—will begin to play a larger part in identifying those scientists who have had or will have a major impact on their fields. Indeed, a new breed of sociometrist is developing, called the scientist of science², that is concerned chiefly with the historical, sociological, economic and behavioural study of science and scientists.

Unfortunately, the measurement of science will not become more precise, even though there is a specialized group doing the measuring, unless more effective measuring techniques are developed and used. Most evaluation procedures available to sociometrists are not only slow and costly, they are also tedious. Such practices as counting the number of papers published have been used because truly objective methods were not available. The exponential growth of scientific research and the increasing number of scientists only make matters worse. It is in meeting this need for an effective, efficient, and unobtrusive³ sociometric tool that citation indexing may find its most important application.

A citation index is an ordered list of cited articles, each accompanied by a list of citing articles. The citing article is identified as a source, the cited article as a reference⁴. The *Science Citation Index* (SCI), published by the Institute for Scientific Information, is the only regularly issued citation index in science. It is prepared by computer and provides an index to the contents of every issue published during a calendar year of more than 2,000 selected journals. Journals covered by the index are chosen by advisory boards of experts in each of the topics represented and by large scale citation analyses.

The entry for a cited article (reference) contains the author's name and initials, the cited reference year, and the publication name, volume, and page number. Under the name of each cited author appears the source article citing this work. This line is arranged by citing author's name, publication, type of source item (article, abstract, editorial and so on), citing year, volume, and page. The searcher starts with a reference or an author he has

identified through a footnote, book, encyclopaedia, or conventional word or subject index. He then turns to the *Citation Index* section of the SCI and searches for that particular author's name. When he has located the name, he checks to see which of several possible references fits the particular one he is interested in. He then looks to see who has currently cited this particular work. After noting the bibliographic citations of the authors who are citing the work with which he started, the searcher then turns to the *Source Index* of the SCI to obtain the complete bibliographic data for the works which he has found.

After finding several source articles, the searcher can use the bibliographies of one or several of these as other entries into the citation index; this process is called "cycling". Since authors frequently write more than one closely related paper, additional articles by the author of the starting reference can also be used as entry points to the index.

Basically, then, the SCI does two things⁵. First, it tells what has been published. Each annual cumulation cites between 25 and 50 per cent of the 5 to 10 million papers and books estimated to have been published during the entire history of science. Second, because a citation indicates a relationship between a part or the whole of a cited paper and a part or the whole of the citing paper, the SCI tells how each brick in the edifice of science is linked to all the others⁶. Because it performs these two fundamental functions so well, important applications for the SCI have been found in three major areas: library and information science, history of science, and the sociology of science.

The SCI was originally designed to be a retrieval tool for use in library and information science work⁷. It has served this purpose very well. The unique retrieval effectiveness of the SCI has already been reported by several investigators⁸. The worldwide adoption of SCI in its short history confirms its ability to augment traditional indexing methods.

Uses in Historical Research

Besides retrieval, other uses for the SCI in library and information science are emerging. Because well over 20 million bibliographic citations have been extracted from more than 1,500,000 source documents, the SCI data base can be utilized to provide definitive studies of journal-to-journal relationships. A recent study by Martyn⁹ illustrated how the SCI data base could be used

to rank British scientific journals and pick out the effective "hard core" of literature. Soon, the Institute for Scientific Information will publish a statistical compilation which will show how often each of 2,000 journals cite one another. This *Source Journal Citation Index* will be complemented by the *Reference Journal Citation Index*, which will show how often each of these 2,000 journals cites any of more than 25,000 other journals.

The suggestion for using citation indexing for historical research came as early as 1955¹⁰. Dr Gordon Allen gave great impetus to this idea when he constructed a bibliographic citation network diagram in 1960 (personal communication from G. Allen). In 1964 the practical methodology was developed to permit the use of citation indexing in sociological and historical research to identify key events, their chronology, their interrelationships, and their relative importance¹¹.

Fig. 1 shows the application of SCI data to create a graphic aid to the study of the history of science. By examining the interconnecting links of scientific events shown in the citation network, it is possible to observe historical and sociological processes at work. It is also easy to identify the nodal publications in the citation network, that is, those that are cited most by others, those that have had the most impact. From Fig. 1 it would be quite reasonable to conclude that whoever published paper number 2 had considerable impact on research involving nucleic acid staining. It is at this point that the SCI begins to serve as an objective sociometric tool; it begins to show who has truly influenced the course of science.

In addition to identifying individuals whose work has had impact on a branch of science, carefully constructed citation networks can help disprove certain prevailing scientific myths. For example, it is commonly believed that Gregor Mendel's breakthrough paper on genetics

was ignored by the scientific community from the time it was presented in 1865 until it was "rediscovered" in 1900. The citation network in Fig. 2 shows, however, that not only was Mendel's work not ignored, but that it was actually cited by at least four different people before 1900. Mendel's work was even cited in an article on "hybridism" in the ninth edition of the *Encyclopaedia Britannica*. One could hardly call that being ignored.

Citation networks can also bring into focus anomalies in the history of scientific development. In Fig. 2, for example, why did Darwin's 1876 paper cite Hoffman but not Mendel? Certainly this is unusual, since Hoffman's paper cites Mendel five times. Inconsistencies like these are clearly identified in citation networks and give impetus and assistance to all types of important historical research.

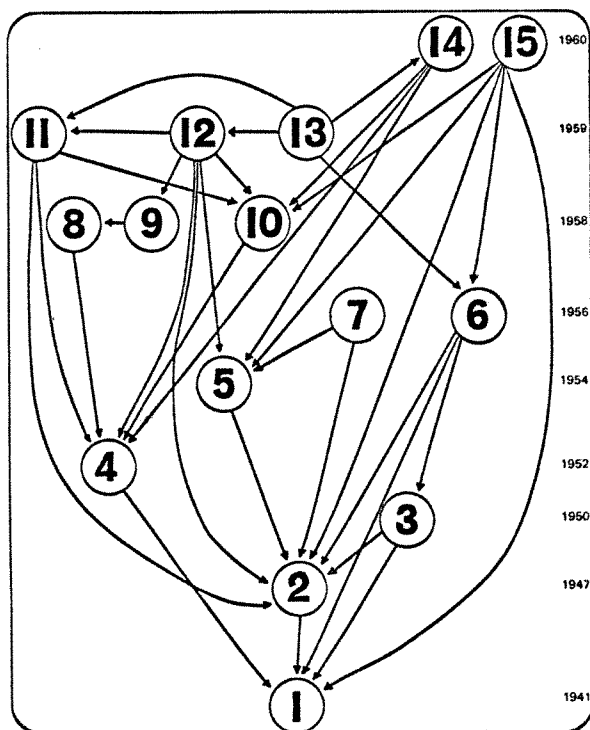

Fig. 1. Citation network of fifteen articles on nucleic acids.

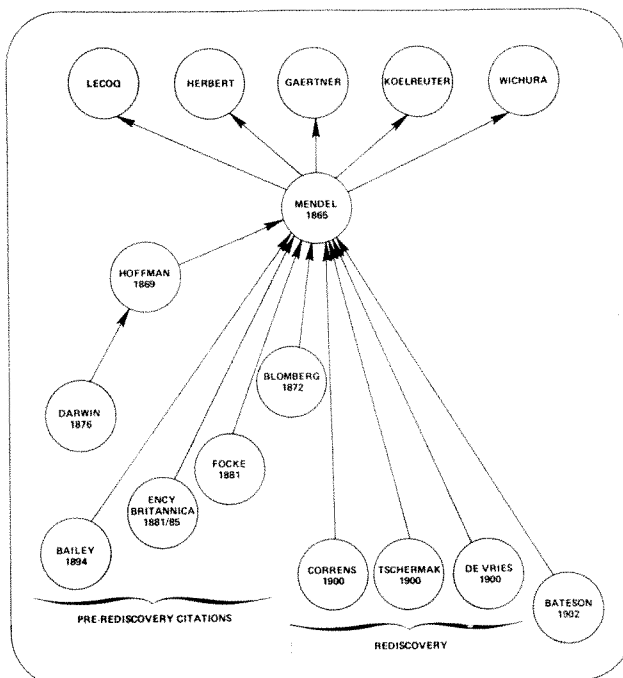

Fig. 2. Citation network showing citations to Mendel before alleged "rediscovery". This was discussed by Zirkle in ref. 11a.

The citation networks shown were produced manually, but further work¹² indicates that such diagrams can be assembled automatically using large computer memories and programs for iterative display of appropriate data. This means that in the near future a historian or sociometrist will be able to sit before a computer console and specify some starting point—a person, a word, a citation, or a place¹³. He will then ask the computer to display a list of pertinent papers. The computer will respond by drawing or displaying a historical road map which will show not merely a list of papers and books, but also a graphical approximation of the history of that subject.

It was a logical step to progress from using the SCI as a sociometric tool in historical contexts to using it to measure current scientific performance¹⁴. Bayer¹⁵, Martino¹⁶, and others have already reported that valid correlations can be obtained between individual performance and citation counts. Perhaps the most dramatic indication of the sociometric power of the SCI was the forecast made in 1968 of those who would win Nobel prizes in 1969¹⁷.

Fig. 3. Fifty most cited authors for 1967, ranked according to total number of times cited.

Predicting Nobel Prize Winners

By using the SCI data base, it was possible to list the fifty most cited authors for 1967 as shown in Fig. 3. Two of the 1969 Nobel prize winners, Derek H. R. Barton and Murray Gell-Mann, appeared on the list. There are about one million scientists in the world and so to produce a list of fifty that contains two Nobel prize winners is no small achievement. It is especially impressive when one considers that the approach is based on a purely objective method which does not require a personality appraisal or a reading of the works by these men.

Although forecasting Nobel prize winners is an interesting exercise, the ability of the SCI to identify those individuals who will make a major impact on science has more practical social and economic consequences. Research administrators in academic, industrial, and government organizations have frequently indicated the need for a tool for identifying such people. Increasingly scarce intellectual and financial resources for supporting research could be managed more efficiently with such an identification tool. Creative people could be identified much earlier in their careers so that they could benefit from special training. Prizes, grants, fellowships and other forms of recognition could be awarded without the wasteful in-fighting and manoeuvring among scientists described by Watson¹.

Another problem facing research administrators is how to determine the directions research should take in the future. The recent summary of the difficulties involved in selecting lunar experiments for the Apollo program¹⁸ is a good current example of this type of dilemma.

In this kind of situation, imaginative use of the SCI data base might contribute to a solution. In the near future ISI will publish what should prove to be a valuable forecasting tool. This will be a regularly published list of the 20,000 papers which are cited most in a given year.

Proper analysis of this information could be a giant step forward in identifying "where the action is" (or should be) in the area of scientific research.

When the *Science Citation Index* was first proposed, its major objective was to break the so-called subject index barrier¹⁹. Out of this bibliographic experiment has evolved a historiographic and sociometric tool of major importance. Like most other scientific discoveries, this tool can be used wisely or abused. It is now up to the scientific community to prevent abuse of the SCI by devoting the necessary attention to its proper and judicious exploitation.

Role of Methionine in the Initiation of Haemoglobin Synthesis

by

RICHARD JACKSON
TONY HUNTER

Department of Biochemistry,
University of Cambridge, Cambridge

The α and β chains of rabbit globin are initiated by the incorporation of a methionine residue in the N-terminal position. This methionine is removed during the early stages of chain growth.

FOR a long time it has not been clear whether a special species of tRNA is required for the initiation of protein synthesis in eukaryotic cells¹. In the particular case of haemoglobin synthesis there have been a number of conflicting reports. On the one hand, it has been claimed that short nascent α chains have a modified and as yet unidentified N-terminal residue². On the other hand, the results of incorporation experiments using tRNA carrying modified valine residues have been taken as an indication that no special initiating tRNA exists other than the valyl-tRNA translating the N-terminal codon³⁻⁵. Consistent with this are the reports that newly synthesized haemoglobin and also the nascent protein chains on reticulocyte ribosomes have valine as the only detectable N-terminal residue⁶⁻⁷.

We report here that methionine is the N-terminal residue of short nascent protein chains bound to rabbit reticulocyte ribosomes. We propose that methionine is incorporated into the N-terminal position of both α and β chains of rabbit haemoglobin during the initiation process of protein synthesis and is removed during the early stages of peptide chain growth.

Isolation of Ribosomes in a Post-initiation State

Our approach was to examine the short nascent peptides found on ribosomes shortly after these ribosomes had initiated new chains. The ribosomes were synchronized in a pre-initiation state by using sodium fluoride to inhibit the initiation of new chains while pre-existing nascent protein was completed⁸⁻¹⁰. The NaF was then removed, thus allowing the initiation of new nascent chains, but the growth of these chains was restricted by the use of inhibitors (for example, sparsomycin). Rabbit reticulocytes from phenylhydrazine treated animals were washed and incubated with 10 mM NaF at 37° C for 30 min in the complete medium containing amino-acids and ferrous ions¹¹. Following this pre-incubation a stroma-free lysate was prepared, gel-filtered on 'Sephadex G-25', and incubated at 37° C in the following conditions: 70 mM KCl, 2.7 mM magnesium acetate, 5 mM 2-mercaptoethanol, 1.8 mg/ml. creatine phosphate, 50 μ g/ml. creatine phosphokinase, 1.0 mM ATP, 0.1 mM GTP and 25 mM Tris-HCl (pH 8.1 at 0° C and pH 7.8 at 37° C), together with the radioactive amino-acid required and complementary unlabelled amino-acids. The incorporation of radioactive amino-acids into protein in such lysates was 80-95 per cent inhibited if 10 mM NaF was added, and was therefore largely dependent on the initiation of new nascent chains¹⁰.

To restrict the growth of these newly initiated chains, sparsomycin¹² was added at a final concentration of 40-140 μ M. After an incubation period of 5-20 min, the ribosomes were isolated by centrifugation at 100,000g through 1 M sucrose containing the buffered salts medium (lacking 2-mercaptoethanol) used in the incubation. The labelled material bound to these ribosomes had the following properties regardless of the labelled amino-acid used: (1) it was precipitated by cetyl trimethyl ammonium

bromide (CTAB), which only precipitates peptides and proteins if they are covalently linked to RNA (unpublished observations of R. J. J.); (2) it has a high reactivity towards puromycin as assayed by precipitation with CTAB; (3) labelled material is almost exclusively (greater than 85 per cent) extracted into the aqueous phase on preparation of the RNA from the ribosomes by phenol extraction at pH 5.2; (4) the puromycyl peptides are extracted to a high degree (60-70 per cent) into ethyl acetate at pH 10 (ref. 13).

Because the normal random length nascent protein formed in the absence of inhibitors was similar with respect to the first two properties, but markedly different in the last two, the product formed in the presence of sparsomycin must be almost exclusively short nascent peptides. The composition and yield of this material were estimated using various individual labelled amino-acids, or a ¹⁴C-amino-acid mixture, followed by hydrolysis of the peptides and separation of the constituent amino-acids. At high concentrations of sparsomycin (140 μ M), methionine and valine were the only amino-acids present in these short peptides. At lower levels (50 μ M), approximately equimolar amounts of methionine, valine and leucine were estimated; and in addition proline, alanine, serine and histidine were found. The yield of methionine residues per ribosome was the same at the two concentrations of sparsomycin. The fraction of ribosomes synthesizing these short peptides was calculated to be 10-15 per cent, which is close to the proportion expected to be active immediately after the removal of NaF⁸⁻¹⁰. These results indicate that the product resembles the N-terminal segments of the α and β chains of rabbit globin except for the presence of a methionine residue (see Fig. 1).

α chain:	Val-	Leu-	Ser-	Pro-	Ala-	Asp-	Lys-	Thr...
	1	2	3	4	5	6	7	8
β chain:	Val-	His-	Leu-	Ser-	Ser-	Glu-	Glu-	Lys...
	1	2	3	4	5	6	7	8

Fig. 1. N-terminal sequences of the α and β chains of rabbit haemoglobin. The sequence of the α chain is that determined by von Ehrenstein¹⁴ and of the β chain by Braunitzer, Best, Flamm and Schrank¹⁴.

Sequence Analysis of the Short Peptides

The homogeneity of the N-terminal sequences of the peptides formed at 40-50 μ M sparsomycin was examined by Edman degradation of the unfractionated material (Fig. 2). The recoveries of radioactivity for each labelled amino-acid were comparable and not a source of selective error. When the peptides were labelled with ³⁵S-methionine, approximately 75 per cent of the radioactivity was released in the first round and the remaining 25 per cent in the second round (Fig. 2). It seems that the efficiency of each cycle of the Edman degradation is approximately 75 per cent in these conditions, and that all the methionine is N-terminal. This view is justified, for Edman degradation of individual peptides separated by electrophoresis gave results identical to the unfractionated material, and no peptide could be found which yielded methionine chiefly in the second round of degradation. Valine was

obtained principally in the second round of degradation, and the remainder was released in the third round (Fig. 2). By the same reasoning, valine was assigned exclusively to the second position. If the same efficiency is maintained in the third cycle of degradation, about 60 per cent of the total leucine and 30 per cent of the histidine occurred in the third position. The proportion of histidine in this position may be seriously underestimated, however, for the extraction of the phenylthiohydantoin derivative of histidine into butyl acetate is not efficient¹⁶.

Although these results show that methionine was found in the N-terminal position and valine in the second position, they do not rule out the possibility that two classes of peptides exist, one with the N-terminal sequence Met-X . . . and the other with the sequence Y-Val This possibility was rigorously excluded by Edman degradation of peptides from which the methionine residue had been cleaved specifically by treatment with cyanogen bromide¹⁷. The efficiency of this cleavage was rather low, but there was a close correlation between the efficiency of cleavage and the proportion of ¹⁴C-valine released one round earlier than normal in the Edman degradation (Fig. 3). Because equimolar quantities of methionine and valine occur in these peptides (see above), this proves unambiguously that methionine and valine residues exist in peptides of sequence Met-Val This sequence does not occur in either chain of completed rabbit haemoglobin¹⁴.

Fig. 2. Edman degradation of short peptide material. For A and B, the labelled peptides were obtained by the following procedure: incubation of lysates from NaF treated cells with the radioactive amino-acid specified, isolation of the ribosomes, extraction of the ribosomal RNA, and treatment with 1 per cent trimethylamine to strip the peptides from rRNA (see text). The three stage Edman degradation was done by the method of Gray¹⁵. After each cycle the released phenylthiohydantoin was extracted into butyl acetate. The butyl acetate extracts and the residue remaining after the third step were dried down, dissolved in acetone and formic acid respectively, and transferred to an aqueous scintillator¹¹. The radioactivity released at each step and that remaining in the residue (R) are expressed as a percentage of the radioactivity recovered. Recoveries are expressed as a percentage of the input radioactivity; it was not possible to estimate the recoveries of the ³H-amino-acids. A, Labelling conditions: incubation for 8 min with 50 μ M sparsomycin (except in iii), and either L-³⁵S-methionine (9 Ci/mole; 3.0 μ Ci/ml. final concentration) or L-¹⁴C-valine (270 mCi/mole; 1.5 μ Ci/ml.). (i) ³⁵S-methionine peptides (recovery 91 per cent); (ii) ¹⁴C-valine peptides (recovery 90 per cent); (iii) ³⁵S-methionine peptides labelled in absence of sparsomycin (recovery 96 per cent). B, Labelling conditions: incubation for 10 min with 40 μ M sparsomycin and either ³⁵S-methionine (4.6 μ Ci/ml.) and L-4,5-³H-leucine (24.3 Ci/mole; 8.0 μ Ci/ml. final concentration), or ¹⁴C-valine (1.7 μ Ci/ml.) and L-2,5-³H-histidine (7.4 Ci/mole; 8.0 μ Ci/ml.). (i) ³⁵S-methionine distribution (recovery 81 per cent); (ii) ³H-leucine distribution; (iii) ¹⁴C-valine distribution (recovery 90 per cent); (iv) ³H-histidine distribution. C, Short peptide material isolated from ribosomes as given above, except that the ribosomes were from whole cells which were incubated with labelled amino-acids in conditions of tryptophan starvation (see text). (i) ³⁵S-methionine labelled peptides (recovery 96 per cent); (ii) ¹⁴C-amino-acid labelled peptides (recovery 70 per cent).

Fig. 3. Edman degradation of labelled peptides after cyanogen bromide treatment. The peptides were obtained by the method described in the text and in Fig. 2. Labelling conditions were 10 min incubation with 40 μ M sparsomycin and either (i) ³⁵S-methionine (4.6 μ Ci/ml.) or (ii) ¹⁴C-valine (1.7 μ Ci/ml.). The peptides were incubated for 24 h at room temperature in (A) 0.4 ml. 70 per cent formic acid or (B) 0.4 ml. 70 per cent formic acid containing 5 mg cyanogen bromide¹⁷. After being vacuum dried three times, the peptides were dissolved in 0.1 ml. 0.01 M HCl and extracted three times with butyl acetate to remove ³⁵S-labelled by-products which might interfere. The final aqueous phase was sampled to assay radioactivity, dried and subjected to Edman degradation as described in Fig. 2. The loss of radioactivity on treatment with cyanogen bromide was 51 and 63 per cent (duplicate samples) in the case of ³⁵S-methionine-labelled peptides, and 7 per cent for ¹⁴C-valine labelled peptides. From these figures an efficiency of cyanogen bromide cleavage of 57 per cent was calculated. The recoveries of radioactivity in the Edman degradation were all greater than 80 per cent. A, Sham treated controls: (i) ³⁵S-methionine distribution; (ii) ¹⁴C-valine distribution. B, Cyanogen bromide treated peptides: (i) ³⁵S-methionine distribution (labelled material remaining after cyanogen bromide treatment.) (ii) ¹⁴C-valine distribution.

Electrophoresis of Short Peptide Products

The peptides stripped from the RNA by exposure to 1 per cent trimethylamine were separated by electrophoresis at pH 3.5, and examined for ³⁵S-methionine distribution by autoradiography (Fig. 4). Some heterogeneity was caused by methionine existing in different states of oxidation, as demonstrated by the simplification obtained by oxidation with air or performic acid before electrophoresis. For example, air oxidation¹⁸ of the material A eliminated the more rapidly migrating components of spots 2 and 4 (see Fig. 4D).

Heterogeneity in the pattern was also inversely related to the concentration of sparsomycin present in the incubation (see Fig. 4A-C). At very high concentrations only two products are formed. One of these is free methionine and its oxidation products (spot 4, Fig. 4). The other (spot 2) had identical mobilities with chemically synthesized methionyl-valine on electrophoresis at pH 3.5 and on chromatography in the system of Waley and Watson¹⁹. As further proof of the structure, it was isolated, labelled with ³⁵S-methionine and ³H-valine and subjected to one cycle of Edman degradation. Of the ³H-valine radioactivity in the aqueous phase after this one cycle, 80-85 per cent was recovered as free valine on electrophoresis at pH 3.5 and then perpendicularly at pH 2.1. The corresponding peptide (spot 2) formed at lower concentration of sparsomycin (Fig. 4B) has also been identified as Met-Val by the same procedure.

A comparison of the peptide products formed at 140 μ M and 50 μ M sparsomycin revealed, first, that the dipeptide Met-Val was the only peptide product formed at the higher concentration, and is one of the peptides found at the lower level of sparsomycin; second, that the yield of methionine residues per ribosome was the same in the two conditions; third, several species of peptides containing methionine were formed at the lower concentration of sparsomycin (Fig. 4B), but Edman degradation of the unfractionated peptides showed that these have the N-terminal sequence Met-Val

As might be expected, the concentration of sparsomycin therefore determined the size of the peptide products but not the N-terminal sequences found. The only peptide

Fig. 4. Electrophoresis of short peptides labelled with ^{35}S -methionine. The peptides were obtained by the following procedure: incubation of a lysate from NaF treated cells for 10 min with ^{35}S -methionine (1.7 $\mu\text{Ci}/\text{ml}$, final concentration) and the sparsomycin concentrations given below, isolation of the ribosomes, extraction of the ribosomal RNA and treatment with 1 per cent trimethylamine to strip the peptides from tRNA. These peptides and a ^{35}S -methionine marker were electrophoresed at pH 3.5 for 1 h at 3 kV on Whatman '3MM' paper. The autoradiogram obtained after 6 days exposure is shown. The positions of neutral amino-acids, histidine and two neutral dipeptides (alanyl-leucine and leucyl-tyrosine) were detected by ninhydrin staining. The sparsomycin concentrations used were (A) 140 μM , (B) 60 μM and (C) 20 μM and the amounts of material applied were 5,350 c.p.m., 30,860 c.p.m. and 10,360 c.p.m. respectively. (D) is 1,700 c.p.m. of the same material as (A) but subjected to air oxidation¹⁸ before electrophoresis. The amino-acids present in the peptides in groups I, II and III were determined separately using pooled peptides labelled with a mixture of ^{14}C -amino-acids at 50 μM sparsomycin. The eluted peptides were hydrolysed in 6 M HCl for 24 h at 110° C; the hydrolysates were mixed with unlabelled amino-acids and subjected to electrophoresis at pH 2 for 25 min at 5 kV followed by descending chromatography in *tert*-amyl alcohol (pH 6.5). All ninhydrin positive spots were eluted and counted by liquid scintillation counting¹¹. The radioactive amino-acids detected in each group are shown in the figure: equimolar amounts are not necessarily present. Compositions were also determined by electrophoresis of peptides labelled with ^{35}S -methionine and ^3H -valine, ^3H -leucine or ^3H -histidine at 50 μM sparsomycin, followed by elution of the various spots and liquid scintillation counting.

product formed at high levels, the dipeptide Met-Val, has been lengthened into oligopeptides of sequence Met-Val . . . under the less stringent restriction of chain growth. Edman degradation of the unfractionated material has demonstrated that these oligopeptides include peptides which have the sequences Met-Val-Leu . . . and Met-Val-His The former must account for about half of the material, for the unfractionated material contained leucine in equimolar amounts with respect to methionine and valine, and 60 per cent of the leucine was found in the third position. The proportion of peptides with the sequence Met-Val-His . . . could not be determined.

The composition of the separated peptides or groups of peptides was examined as described in Fig. 4. All the peptides of high mobility (group I) contained histidine at the same ratio of methionine to histidine, and because histidine occurred only in this group of peptides, at least some must have the sequence Met-Val-His . . . established above. Some of these peptides contained leucine (for example, spot 1) and serine. The ^{35}S -methionine label in all of them, and the ^3H -leucine label in spot 1, migrated towards the cathode at pH 6.5. All the peptides of lower mobility than the dipeptide Met-Val contained leucine, and some also had proline and alanine residues. Edman degradation showed that the leucine in this group of peptides was almost exclusively in the third position. These peptides therefore largely account for the half of the material which has been shown to have the sequence Met-Val-Leu and the mobility of spot 3 suggests that it may be the tripeptide Met-Val-Leu.

An approach comprising Edman degradation of the unfractionated peptides and certain groups of separated peptides, together with analysis of the composition of separated peptides, has therefore established that the products formed at 50 μM sparsomycin consist of free methionine, the dipeptide Met-Val and two main classes of oligopeptides: (a) those which lack histidine and have the sequence Met-Val-Leu . . . and therefore probably represent α chain peptides, and (b) those which have the sequence Met-Val-His . . . but lack proline and alanine, and therefore seem to be β chain peptides (see Fig. 1).

N-Terminal Methionine of Nascent Protein from Intact Cells

We next examined whether methionine was in the N-terminal position of short nascent globin chains synthesized in intact cells. To obtain ribosomes carrying mainly short nascent chains, the cells were starved of tryptophan by pre-incubation at 37° C for 40 min in the complete medium lacking tryptophan¹¹. They were then incubated for 4 min with either ^{14}C -amino-acid mixture or ^{35}S -methionine, before arresting protein synthesis by the addition of cold saline containing actidione (1 mg/ml.)¹¹. The ribosomes were prepared as described. The nascent protein was equally reactive towards puromycin, whether labelled with ^{35}S -methionine or with ^{14}C -amino-acids. When the short peptides were isolated by extraction of the RNA from the ribosomes, 31 per cent of the ^{35}S -methionine was recovered as opposed to 19 per cent of ^{14}C -amino-acid label. Edman degradation of this short peptide material showed that most of the methionine was in the N-terminal position (Fig. 2), and electrophoresis at pH 3.5 showed that it was not in the form of free methionine but was in peptides which gave a pattern similar to that of the product formed *in vitro*. It was calculated that not less than 25 per cent of the total ^{35}S -methionine in this nascent protein labelled *in vivo* was in the N-terminal position.

Fate of the N-Terminal Methionine Residue

Because valine is found in the N-terminal residue of most nascent chains⁶⁻⁷, the methionine in the N-terminal position of short chains must be removed during the early stages of peptide growth. To study this we incubated ribosomes with cell sap in conditions for extension and completion of the chains, using ribosomes which carried exclusively short labelled nascent chains (Fig. 5). The radioactivity of peptidyl tRNA (CTAB-precipitable radioactivity) and of long peptides (acid-precipitable radioactivity after NaOH treatment) was assayed. The excess of CTAB-precipitable radioactivity over acid-precipitable radioactivity at the start of the incubations represents short peptides attached to RNA. The decrease in CTAB precipitable radioactivity during the incubation represents the release of the protein from RNA presumably as completed chains. The increment in acid-precipitable

radioactivity must represent the entry of label from short peptides into long peptides, that is, extension of short nascent chains. Valine and other amino-acids were transferred with reasonable efficiency into stable long peptides, but the transfer of the methionine was poor (Fig. 5), although it did appear temporarily in the long peptides after short incubation periods. Because these changes were inhibited by sparsomycin but not by NaF they are dependent on protein synthesis but not on initiation of new peptide chains. The methionine residue, which occupies only the N-terminal position of these short nascent chains, is therefore conserved in the earliest stages of chain growth at least to the point when the polypeptide becomes acid precipitable, and then is removed soon afterwards.

The same experiment was performed using the ribosomes which carried nascent chains labelled with ^{35}S -methionine during incubation of intact cells. Again there was an early but transient increment in the acid-precipitable radioactivity showing the retention of the N-terminal methionine for only a limited period of peptide chain growth.

When the yield of the various tryptic peptides obtained from nascent globin was measured¹¹, $\alpha\text{T}1$ and $\beta\text{T}1$ were found in especially low yield if the ribosomes were situated chiefly near the initiation site (that is, in tryptophan starved cells), but in the expected amounts if the ribosomes were chiefly at the distal end of the mRNA (that is, shortly after the addition of NaF). The presence of N-terminal methionine on short nascent chains accounts for this previously unexplained deficit dependent on the average chain length. Because the yield of these two peptides was 10–15 per cent lower than expected when the ribosomes were randomly distributed¹¹, N-terminal methionine must be removed when the nascent chains attain a length of fifteen to twenty residues. This estimate is consistent with the retention of N-terminal methionine when relatively short synthetic polynucleotides were used as templates²⁰. Because a length of nascent protein corresponding to about thirty residues is protected against external proteolytic enzymes^{3,21}, it is possible that the methionine aminopeptidase is a ribosomal protein. On the other hand, we find that reticulocyte ribosomes do not remove N-terminal methionine from puromycin peptides (unpublished observations).

Although the sequential use of NaF followed by sparsomycin provides the most convenient system in that a good yield of a relatively homogeneous short peptide product was obtained, there is a risk that such inhibitors may induce artefacts. But the use of 5'-guanylyl-methylene-diphosphonate (in the absence of GTP), or of diphtheria toxin and NAD, instead of sparsomycin gave a material which was similar in composition, electrophoretic mobility and in having the N-terminal sequence Met-Val... but in reduced yield. If no inhibitor of chain elongation was used, the ribosomes nevertheless carried some short peptides with N-terminal methionine (Fig. 2). Finally, the observation that methionine is in the N-terminal position of short chains labelled in the intact cell validates the results obtained with the *in vitro* system.

Most previous studies of initiation in reticulocytes do not conflict with our conclusion. Valine has been reported to be the N-terminal residue of nascent globin chains⁵⁻⁷, as we have ourselves found by the same methods. But the slightly lower yield expected if 10 per cent of the chains have an N-terminal methionine residue has actually been noted by others^{5,7}. The apparently contradictory claim that amino-acids other than valine were not found in the N-terminal position of nascent chains⁶ can be explained by the absence of ^{14}C -methionine from the ^{14}C -amino-acid mixture used.

The only clear contradiction is the ability of 2-hydroxyisovaleryl-tRNA to insert 2-hydroxyisovaleryl groups into globin presumably in the N-terminal position^{3,4}. Our results imply that initiation by this modified valine

Fig. 5. Re-incubation of ribosomes carrying short nascent peptides. A lysate from NaF treated cells was incubated as given in the text for 8 min with 40 μM sparsomycin and either (A) a mixture of fourteen uniformly ^{14}C -labelled L-amino-acids (2 mCi/mg; 1.4 $\mu\text{Ci}/\text{ml}$, final concentration) plus excess (100 μM) unlabelled valine, (B) ^{14}C -valine (1.5 $\mu\text{Ci}/\text{ml}$) or (C) ^{35}S -methionine (3.0 $\mu\text{Ci}/\text{ml}$). The ribosomes isolated from these incubations (see text) were re-incubated with fresh gel-filtered cell sap (100,000g supernatant) in the conditions given in text except that all twenty amino-acids were present in the unlabelled form. CTAB-precipitable radioactivity ($\times-\times$) was estimated in 0.05 ml. samples by the addition of 1.5 ml. 2 per cent CTAB and 1.5 ml. 0.5 M sodium acetate-acetic acid buffer pH 5.2 containing 1 mg/ml. carrier yeast RNA. The precipitate was filtered on glass fibre filters and washed with water. Acid-precipitable alkali-stable radioactivity ($\circ-\circ$) was measured in 0.05 ml. samples by the addition of excess acid acetone (1 per cent conc. HCl) and isolation of the precipitate by centrifugation. The protein was dissolved and incubated at 37°C for 30 min in 0.3 M NaOH containing the appropriate unlabelled amino-acid at approximately 1 mg/ml., then reprecipitated by the addition of 8 per cent trichloroacetic acid also containing the appropriate unlabelled amino-acid. The precipitate was filtered on glass fibre filters and washed with trichloroacetic acid. The filters were glued to cardboard disks, dried, and radioactivity was counted in a Nuclear Chicago gas flow counter with an efficiency of approximately 22 per cent. Isolated points marked S refer to incubations with 50 μM sparsomycin, and those marked F to incubations with 10 mM NaF. In 20 min incubation with ^{14}C -leucine and nineteen corresponding unlabelled amino-acids in the same conditions, the following increments in acid-precipitable radioactivity were noted: (A) 84 c.p.m., (B) 72 c.p.m., (C) 127 c.p.m. and control untreated ribosomes 765 c.p.m. per A_{260} unit of ribosomes incubated.

residue must be abnormal, and it is therefore of interest that only a small proportion of the chains were initiated in this way³.

Our results provide the necessary evidence that the first of the three models of initiation proposed by Smith and Marcker²² is correct and valid for protein synthesis on natural mRNA: an N-terminal methionine residue is incorporated during the initiation of α and β chains of rabbit globin and is removed during the early stages of chain elongation. This conclusion seems broadly in agreement with forthcoming reports from two independent sources^{23,24}. It remains to be proved whether this mechanism of initiation is generally applicable to all eukaryotic cells. It is of interest that methionine is rarely found in the N-terminal position of completed proteins in eukaryotic cells²⁵, and the initiation of those proteins which have N-terminal methionine—for example, β chains of certain haemoglobins²⁶—clearly deserves special investigation.

The theory of Smith and Marcker²² demands that the methionine residues which initiate rabbit globin chains are unmodified and are furnished by a particular species of tRNA. We shall examine the validity of this proposition elsewhere.

We thank Dr A. J. Munro and Peter Lorkin for advice, Mr M. J. Brittain for technical assistance, Professor K. A. Marcker, Alan Smith and Dr H. F. Lodish for allowing us to see their manuscripts before publication, and Professor F. G. Young for encouragement. We were supported by research fellowships from Pembroke College (R. J. J.) and Christ's College (A. R. H.) and acknowledge

a grant for expenses from the British Empire Cancer Campaign.

Transient Incorporation of Methionine at the N-Terminus of Protamine Newly Synthesized in Trout Testis Cells

by

DONALD T. WIGLE

GORDON H. DIXON

Evidence is obtained in another eukaryotic system for the universal role of methionine as the initiating amino-acid in protein synthesis.

N-FORMYLMETHIONYL-tRNA_f was discovered by Marcker and Sanger in 1964 (ref. 1) and since then has been established as the initiator of protein synthesis in bacteria²⁻⁴ and implicated in mitochondrial and chloroplast protein synthesis^{4,5}, the involvement of 70S ribosomes being common to all these systems. The initiation mechanism on the 80S ribosomes in eukaryotic cell cytoplasm is known to involve initiation factors^{6,7} but a role for a specific initiator tRNA has not been demonstrated. Two species of Met-tRNA have been found in the cytoplasm of guinea-pig liver⁸ and yeast⁹; one of these, Met-tRNA₁, can be formylated by purified *Escherichia coli* transformylase in the presence of N¹⁰-formyltetrahydrofolate but no endogenous transformylase activity has been detected in the cytoplasm from which these tRNAs were extracted. Met-tRNA₁ from both systems binds to ribosomes in the presence of the initiator codons AUG and GUG; the yeast Met-tRNA₁ also binds in the presence of UUG and was shown to be active in a cell-free system derived from *E. coli* primed with RNA from bacteriophage f2 (ref. 9). The rapid rate of formation of methionyl-puromycin with the liver Met-tRNA₁ suggested that it was bound at the peptidyl site on the ribosome¹⁰. Met-tRNA₁ therefore resembles *E. coli* Met-tRNA_f, but attempts to demonstrate a formylated Met-tRNA in eukaryotic cell cytoplasm have not been successful.

We discuss here the role of methionine in the biosynthesis of protamine in testis cells of the rainbow trout (*Salmo gairdneri*). Protamines are the basic proteins bound to DNA in the nuclei of sperm cells of most higher organisms. By contrast with mammalian testis, the fish testis develops quite synchronously from a thread-like structure composed chiefly of spermatogonial cells to the large adult organ containing chiefly spermatids and mature sperm. Rainbow trout protamine has a molecular weight close to 5,000 and three components have been purified and sequenced by Ando and Watanabe¹¹. There are 31-32 residues with arginine occupying 21-23 of the positions; proline is N-terminal in each component

and acidic, aromatic and sulphur-containing amino-acids are absent.

Protamine is synthesized in the cytoplasm of testis cells at the spermatid stage of differentiation; this synthesis occurs on 120S disomes composed of 77S ribosomes¹². Newly synthesized protamine is rapidly transported into the nucleus and thence into the chromatin where it replaces the histones in a definite order¹³. The synthesis is very sensitive to inhibition by cycloheximide and is also inhibited by puromycin¹⁴.

Methionine Incorporation

Fig. 1 shows incorporation of [¹⁴C-methyl]-methionine into testis histones and protamine; the latter forms the second major peak in the elution profile. An aliquot of this labelled protamine was electrophoresed in a starch-urea-aluminium lactate gel¹⁵; all of the radioactivity had the same mobility as an unlabelled protamine marker or moved just behind it. Newly synthesized protamine is phosphorylated^{15,17} and is known to run more slowly towards the cathode at the pH of the gel (3.4) than older dephosphorylated protamine¹⁸ which is the predominant form in the marker. It is therefore clear that the ¹⁴C-methyl label is incorporated into protamine.

A second aliquot of the labelled protamine was hydrolysed with 6 M HCl at 110° C for 22 h and the resulting mixture of free amino-acids electrophoresed at pH 1.9; the radioactivity had the same mobility as an unlabelled methionine marker. After performic acid oxidation and electrophoresis at pH 1.9, the label moved with an unlabelled methionine sulphone marker. Thus the ¹⁴C-methyl label must have been incorporated into protamine as intact methionine.

Methionine is N-Terminal

To determine whether the incorporated methionine was N-terminal, Edman degradation and dansylation were performed on purified ³⁵S-methionine labelled protamine. Table 1 shows that 75-90 per cent of the label can be

Table 1. EDMAN DEGRADATION OF ^{35}S -METHIONINE LABELLED PROTAMINE

Exp.	Aqueous phase (c.p.m.)	Ethyl acetate phase	PTH-Methionine (per cent)
1	1,660	14,080	89
2 (a)	5,568	17,561	76
(b)	5,214	13,523	72

Aliquots of ^{35}S -methionine labelled protamine were dissolved in 100 μl . of 50 per cent aqueous pyridine and 100 μl . of pyridine-water-N-ethylmorpholine buffer (4:4:1) (NEMO). Phenylisothiocyanate (100 μl .) was added, mixed and deoxygenated by bubbling nitrogen through the solution. The tubes were sealed and incubated at 37° C for 3 h; they were then extracted three times with benzene and lyophilized. Cyclization was performed with anhydrous trifluoroacetic acid at 37° C for 1 h. The samples were lyophilized, redissolved in water and extracted three times with 5 volumes of ethyl acetate; the extracts were pooled, lyophilized, treated with 1 M HCl at 80° C for 15 min and re-lyophilized. Aliquots of the aqueous and ethyl acetate phases were counted in Bray's solution; an aliquot of the ethyl acetate extractable material was subjected to thin-layer chromatography on silica gel with the solvent heptane-n-butanol-formic acid (100:60:18) for 2 h. The gel was scraped off the plate at 0.5 cm intervals and counted in toluene scintillation fluid.

recovered in the ethyl acetate phase after one Edman degradation. This labelled PTH derivative co-chromatographed with a PTH-methionine marker on thin-layer chromatography (legend to Table 1). After dansylation of ^{35}S -methionine labelled protamine and separation of the acid hydrolysate by electrophoresis at pH 4.38 (ref. 19), up to 70 per cent of the label was recovered as dansyl- ^{35}S -methionine. The lack of solubility of protamine in the solvents used in these N-terminal methods probably explains the failure to recover closer to 100 per cent of the label.

Structure of the Methionine Peptide

When ^{35}S -methionine labelled protamine from cell incubations is digested with trypsin, a labelled basic peptide, A, is seen (Fig. 2) after high-voltage electrophoresis at pH 3.6 and autoradiography. A trace of a slightly basic peptide has been seen occasionally, but both peptides change mobility after acetylation, indicating that neither has a blocked N-terminus. As shown in Fig. 2, further digestion of peptide A with carboxypeptidase B yields a labelled peptide, B, which has the same electrophoretic mobility as the Met- ^{14}C -Pro marker (see legend to Fig. 2), and some intact peptide A remains. The electrophoretic behaviour of A and its carboxypeptidase B product, B, is consistent with the structures Met-Pro-Arg for A and Met-Pro for B. Deformylation of the N-Formyl- ^{14}C -Met-Pro-Arg marker caused it to streak during electrophoresis; ^{35}S -methionine-labelled protamine from a cell incubation was therefore formylated chemically in order to compare the N-formyl labelled peptides derived from it with N-formyl marker peptides.

Fig. 1. A cell suspension was prepared from 25 g of testis at a late stage of development using Hanks's balanced salt solution; the cells were incubated with 1 $\mu\text{Ci/ml}$. of [^{14}C -methyl]-methionine (11 mCi/mmol) for 2 h at 20° C. The cells were washed and homogenized in saline-EDTA (0.075 M NaCl, 0.024 M ethylenediaminetetraacetic acid, pH 8) and nuclei sedimented at 3,000g for 10 min; the nuclear pellet was extracted twice with 0.2 M sulphuric acid and the acid-soluble proteins precipitated after addition of 4 volumes of ethanol at -20° C overnight. The precipitate was centrifuged, redissolved and applied to a 'Bio-Gel P-10' column (5 \times 45 cm) which was eluted with 0.2 M acetic acid; 12 ml. fractions were collected and 0.5 ml. of each was counted in Bray's scintillation fluid.

Fig. 2. Autoradiogram of digests of labelled protamine from a cell incubation. 20 g of hormonally induced trout testis was incubated in 40 ml. of Hanks's solution with 20 $\mu\text{Ci/ml}$. of ^{35}S -methionine (500 mCi/mmol) at 18° C for 3 h. Protamine was extracted, purified and a portion digested with porcine trypsin (1 μg enzyme/20 μg sample) at 37° C for 4 h yielded peptide A; further digestion with carboxypeptidase B (1 μg enzyme/ μg sample) at 37° C for 8 h yielded peptide B together with intact A. MP is the Met- ^{14}C -Pro marker. Electrophoresis was at pH 3.6 in pyridine-acetic acid-water (1:10:89) for 1 h at 40 V/cm. The electrophoretogram was exposed to Kodak 'Royal Blue' X-ray film for 6 days. Met- ^{14}C -Pro and its formylated derivative were synthesized by coupling *tert*-butoxycarbonylmethyl-N-hydroxysuccinimide ester to ^{14}C -proline²⁰; the blocking group was removed with anhydrous trifluoroacetic acid (37° C, 1 h) and was purified by high-voltage electrophoresis at pH 3.6. Met- ^{14}C -Pro was eluted from the paper and a portion was formylated by the mixed anhydride method of Sheehan and Yang²¹. Because protamine has a single N-terminal secondary amino group and no lysine, it is possible to couple amino-acids specifically to the N-terminus without blocking any groups on the protamine. Thus ^{14}C -methionine was formylated and coupled to N-hydroxysuccinimide using dicyclohexylcarbodiimide as the condensing agent; the active ester was then reacted with protamine in water-ethanol-dioxane (7:2:2) at room temperature overnight. The product was incubated at pH 10 and 37° C for 30 min to de-esterify any serine residues that might have reacted with the active ester. The N-formylmethionyl-protamine was then purified by chromatography on 'Sephadex G-10' and digested with trypsin (1:20) at 37° C for 4 h in 0.2 M ammonium bicarbonate, and a portion of this digest was deformylated with anhydrous 1 M HCl in methanol at 50° C for 1 h. Because the N-terminal sequence of protamine is Pro-Arg-Arg...¹¹, the above procedures yielded the tryptic peptide, N-formyl- ^{14}C -Met-Pro-Arg and its deformylated derivative, ^{14}C -Met-Pro-Arg.

Formylated ^{35}S -methionine labelled protamine was digested with trypsin or trypsin followed by carboxypeptidase B and the digests were electrophoresed at pH 3.6. Trypsin alone yielded a neutral or slightly basic peptide, A_r, which had the same mobility as the N-Formyl- ^{14}C -Met-Pro-Arg marker; this was confirmed by re-electrophoresis at pH 1.9. Trypsin plus carboxypeptidase B gave a labelled acidic peptide, B_r, which migrated together with the N-Formyl-Met- ^{14}C -Pro marker; this was confirmed by re-electrophoresis at pH 6.5 (Fig. 3a) and descending chromatography (Fig. 3b). Clearly therefore the methionine incorporated into protamine *in vivo* is present in the sequence, Met-Pro-Arg....

Role of Methionine

It was of interest to see if methionine is incorporated into the several components of protamine^{11,12} rather than a single minor component. Cells were incubated with ^{35}S -methionine and protamine was purified and chromatographed on a CM-cellulose column eluted with a linear gradient of lithium chloride¹². Fig. 4 shows six peaks of radioactivity extending across the absorbance profile of the carrier protamine. As mentioned previously, newly synthesized protamine is phosphorylated on its seryl residues; this modification affects the behaviour of protamine on CM-cellulose¹⁷. After digestion with *E. coli* alkaline phosphatase and re-chromatography on CM-cellulose, ^{35}S -methionine labelled protamine still exhibited

Fig. 3. *a*, Autoradiogram of re-electrophoresis of peptide B₁ from a trypsin digest of chemically formylated ³⁵S-methionine labelled protamine. N-Formyl-Met-¹⁴C-Pro marker was applied at 2 and the digest at B_F. Electrophoresis was at pH 6.5 in pyridine-acetic acid-water (10:0.4:89.6), for 1 h at 50 V/cm. The electrophoretogram was exposed to X-ray film for 7 days. *b*, Descending chromatography. Peptide B₁ and the N-formyl-Met-¹⁴C-Pro marker were cut out of the paper from which the autoradiogram in *a* was obtained, sewn into a new sheet of Whatman '3 MM' chromatography paper and subjected to descending chromatography in butanol-acetic acid-water-pyridine (15:3:12:10) for 16 h. The chromatogram was exposed to X-ray film for 5 days.

six peaks of label across the absorbance profile. Methionine must have been incorporated into several protamine components therefore and because tryptic digestion of whole protamine gave only Met-Pro-Arg, in every component the incorporation must have been at the N-terminal position.

If methionine has a role in initiation of protamine synthesis, its presence at the N-terminus should be transient as it is in bacterial systems. To test this, testis cell suspensions were pulsed with ³⁵S-methionine and ³H-arginine and then chased in fresh medium containing the unlabelled amino-acids. Fig. 5 reveals that incorporated arginine is stable during the course of the incubation whereas the methionine is chased out, at least partially. In a second experiment the ratio of ³⁵S-methionine to ³H-arginine in protamine components was examined following separation of newly synthesized protamine on starch-urea-aluminium lactate gels¹⁶ and counting of the radioactivity in the sliced gel. The methionine: arginine ratio approached zero 60 min after the chase began. These results show that the N-terminal methionine is removed after chain completion, but they do not eliminate the possibility that some removal occurs before chain completion.

Extracts of trout testis contain an enzyme activity that can cleave the Met-Pro peptide bond; Table 2 demonstrates the presence of this enzyme activity in nucleoplasm, high-speed supernatant and in the ribosomal wash. The testis extracts are also active against ³⁵S-methionine labelled protamine, but the presence of other proteases in the crude preparations which fragment protamine requires that the Met-Pro hydrolysing activity be purified before its specificity and other properties can be tested. It is possible, however, that the activity detected above is due to a specific methionyl-aminopeptidase responsible for removing

methionine from the N-terminus of protamine and perhaps other proteins.

Inhibitors

Methionine incorporation into protamine was found to be very sensitive to inhibition by cycloheximide with 50 per cent inhibition at less than 10⁻⁷ M. This extreme sensitivity to cycloheximide is characteristic of eukaryotic cytoplasmic protein synthesis and has been described previously for arginine incorporation into protamine¹⁴. Cycloheximide inhibits both chain initiation and elongation²², so that the great sensitivity of methionine incorporation to this inhibitor rules out a mechanism involving N-terminal addition of amino-acids as described for *E.*

Fig. 4. Elution profile of ³⁵S-methionine labelled protamine on a CM-cellulose column eluted with a linear gradient of lithium chloride¹⁴. A cell suspension was prepared from 20 g of rainbow trout testis in which spermatogenesis was artificially induced with injections of pituitary extract from *S. oncorhynchus*²³. The cells were incubated with ³⁵S-methionine (500 mCi/mmol) at 20 μ Ci/ml. for 3 h at 18 $^{\circ}$ C; the cells were washed, homogenized in 50 mM Tris-HCl, 5 mM magnesium acetate, 25 mM KCl, 0.25 M sucrose (pH 7.6) (TMKS) and nuclei were pelleted at 3,000g for 10 min. The nuclei were extracted twice with cold 0.2 M HCl, the extract was neutralized with LiOH and applied to a CM-cellulose column (1.5 \times 35 cm) and eluted with a LiCl gradient: the protamine region was pooled, desalted, lyophilized and reappplied to a second CM-cellulose column (2.5 \times 26 cm) and eluted with a linear gradient generated from 600 ml. each of 0.6 and 1.3 M LiCl with the result shown. 8 ml. fractions were collected and 0.3 ml. of each was counted in Bray's scintillation fluid; salt concentration was measured using a conductivity meter and reference to standard solutions of LiCl.

Table 2. Met-¹⁴C-Pro HYDROLYSIS

Cell fraction	Percentage hydrolysed in 45 min at 16° C	Relative activity*	Percentage total
(1) High-speed supernatant	73.9	100	57
(2) Nucleoplasm	65.8	50	28
(3) Ribosome wash	53.4	27	15

* Corrected for volume of extract per g of testis.

Enzyme extracts were prepared by homogenizing October-stage trout testis in TMKS containing 10^{-4} M dithiothreitol; nuclei were pelleted at 1,500g for 10 min, mitochondria at 20,000g for 30 min and ribosomes at 25,000 r.p.m. in the Spinco 'SW-27' rotor for 4 h. Nuclei and mitochondria were lysed in TMK and centrifuged at 20,000g for 20 min; the supernatants were saved. Ribosomes were washed with 1 M NH_4Cl in TMK overnight; the suspension was centrifuged at 26,000 r.p.m. in the 'SW-27' rotor for 6 h and the supernatant saved. All extracts were precipitated at 90 per cent saturation with $(\text{NH}_4)_2\text{SO}_4$, the precipitate was redissolved in TMK (pH 7.0) and dialysed against three changes of TMK; material precipitating during dialysis was removed by centrifugation. 50 μl aliquots of the extracts were incubated with 50 μl of Met-¹⁴C-Pro in TMK for 45 min at 16° C and the reaction was stopped by chilling and adding to 10 μl 1 M KOH. The samples were electrophoresed at pH 3.6 and 40 V/cm for 45 min; products were located by autoradiography; corresponding areas were cut out and counted in toluene scintillation fluid.

coli^{23,24} and rat liver²⁵. Insensitivity of protamine synthesis to all but high levels of chloramphenicol¹⁴, together with work on the intracellular location of protamine synthesis^{12,26}, seems to eliminate a mitochondrial site of synthesis.

Nascent Peptides

Testis cells were incubated with ³⁵S-methionine for 20 min at 15° C, and ribosomes were prepared and fractionated by centrifugation on a linear gradient of sucrose, with the result illustrated in Fig. 6. Methionine is incorporated generally across the polysome region with the specific activity (c.p.m. ³⁵S-methionine per A_{254}) increasing with the size of the polysome. Because protamine synthesis has been shown to occur on disomes¹², the monosome and disome peaks in the gradient above were pooled and the ribosomes pelleted by centrifugation; ribosome-bound nascent peptides were released, digested with trypsin and a portion was further digested with carboxypeptidase B; the digests were electrophoresed at pH 3.6 with marker peptides. The label was present in the neutral region and in peptides that had the same

Fig. 5. Pulse-chase experiment. A cell suspension was prepared from 15 g of naturally maturing trout testis with 10 ml. of Hanks's. The suspension was divided into two: 4 $\mu\text{Ci}/\text{ml}$. of ³⁵S-methionine (573 mCi/mole) was added to one half and 4 $\mu\text{Ci}/\text{ml}$. of ³H-arginine (1.2 Ci/mole) to the other. Incubation was at 18° C for 10 min; the cells were chilled, washed and resuspended in 20 ml. of Hanks's medium which was 1 mM in unlabelled methionine and arginine, and incubation was continued at 18° C. 5 ml. aliquots were removed starting immediately after resuspending and were frozen in a bath of solid CO_2 ; these were homogenized in saline-EDTA and nuclei were pelleted at 3,000g for 10 min and extracted twice with 0.2 M HCl. The acid extracts were neutralized with LiOH and applied to CM-cellulose columns (1.5 × 5 cm), eluted with 0.75 M LiCl, washed with water and re-eluted with 0.2 M HCl. The acid eluate containing the protamine was lyophilized and then further purified by chromatography on a 'Bio-Gel P-10' column (2.6 × 15 cm) in 0.2 M acetic acid. The protamine peaks were lyophilized and redissolved in distilled water, absorbance at 230 nm was measured, and aliquots were counted in Bray's solution. Specific activity was calculated as c.p.m. of ³⁵S-methionine per A_{230} unit of protamine.

Fig. 6. Ribosomes from ³⁵S-methionine incubation fractionated on a sucrose gradient. A cell suspension from 12 g of induced trout testis was incubated at 15° C for 20 min with ³⁵S-methionine (690 mCi/mole) present at 20 $\mu\text{Ci}/\text{ml}$.; at 15 min, cycloheximide was added to a final concentration of 2×10^{-4} M. The cells were washed and then homogenized in TMKS; the homogenate was centrifuged at 15,000g and then homogenized in TMK; 20 per cent in TMK (TMKS minus sucrose) was added to the supernatant to give a final concentration of 0.5 per cent and centrifuged at 15,000g for 20 min. The supernatant was layered over 2 ml. of 30 per cent sucrose in 13 ml. tubes and centrifuged at 60,000 r.p.m. in the Spinco 'L2-45' rotor for 2.5 h. The supernatant was aspirated and the pellet washed gently with TMK; one-third of the ribosomes were resuspended in 1 ml. TMK and layered over a 35 ml. 10–30 per cent linear gradient of sucrose in TMK generated by a Beckman density-gradient former ('DGF-IM-3'). Centrifugation was at 25,000 r.p.m. in the Spinco 'SW-27' rotor for 3.5 h at 4° C; the centrifuge was stopped without the brake, the tubes punctured and 1 ml. fractions collected. The absorbance at 254 nm was measured and the radioactivity in 200 μl aliquots counted in Bray's solution.

mobilities as Met-Pro and Met-Pro-Arg markers; these labelled areas were cut out, sewn to a new sheet of paper and re-electrophoresed at pH 1.9 with markers. This procedure showed that the neutral material is free methionine and confirmed that the other two peptides are Met-Pro and Met-Pro-Arg; there was no evidence of labelled material corresponding to formylated marker peptides. This absence of formylated nascent peptides suggests that either the methionine is never formylated or the formyl group must be removed early, rapidly and completely on the ribosome.

¹⁴C-Formate is incorporated into protamine by testis cells *in vitro*. Protamine labelled in this manner was hydrolysed with 6 M HCl at 110° C for 16 h; the label was not volatile and was found to have the electrophoretic mobility of serine at pH 1.9. Presumably this is because of the presence in trout testis of a hydroxymethyl transferase which can synthesize serine from glycine and N⁵,10-methylene tetrahydrofolate, the methylene moiety being derived from formate. Attempts to find ¹⁴C-formate or ³⁵S-methionine-labelled formylated nascent peptides either on the ribosomes or in the high-speed supernatant after puromycin release were unsuccessful.

The transient incorporation of methionine at the N-terminus of several protamine components suggests that it has a role in the initiation of biosynthesis of this protein. The ease with which this incorporation can be detected may be related to the unusual properties of protamine. Rich, Eikenberry and Malkin^{27,28} have

demonstrated a shielding effect of the ribosome on nascent proteins; ribosome-bound nascent chains 30–35 residues long were found to be protected from external proteolytic attack. Protamine, 31–32 residues long, may therefore be protected from attack by a putative methionine-removing enzyme until the chain is completed and released into the cytoplasm. Other contributory circumstances may be the difficulty of cleavage of the Met-Pro peptide bond; in general, X-Pro bonds are resistant to many proteases with the possible exception of imidodipeptidase³⁰; but this enzyme is specific only for dipeptides. Also, as shown by Ling and Dixon²⁶, at the stage of differentiation at which protamine synthesis is maximal, there has been a considerable reduction of the spermatid cytoplasm and ribosome content. The levels of cytoplasmic enzymes, including the methionine-removing enzyme, may therefore become limiting at this stage.

The involvement of methionine in the initiation of protein synthesis in eukaryotic cells is not yet firmly established although the presence of a formylatable species of Met-tRNA with the properties of an initiator tRNA in mouse ascites cells^{31,32} is certainly consistent with such a role. Our observations of methionine involvement in the synthesis of the very unusual, sperm-specific polypeptide, protamine, suggest that such a mechanism may be of widespread importance in eukaryotes, and in the special circumstances of protamine biosynthesis, where removal of the N-terminal methionyl residue may become limiting, the transient incorporation of this amino-acid is readily observed.

Cleavage of Structural Proteins during the Assembly of the Head of Bacteriophage T4

by

U. K. LAEMMLI

MRC Laboratory of Molecular Biology,
Hills Road, Cambridge

Using an improved method of gel electrophoresis, many hitherto unknown proteins have been found in bacteriophage T4 and some of these have been identified with specific gene products. Four major components of the head are cleaved during the process of assembly, apparently after the precursor proteins have assembled into some large intermediate structure.

BACTERIOPHAGES of the T-even type are complex structures containing many different proteins and specified by many genes. Using an improved technique of electrophoretic separation I have found that the phage particle contains at least twenty-eight components, eleven of which are in the head. In the course of identifying the genes specifying these proteins I discovered that four major components of the head, the product of gene 22, 23, 24 and a protein called IP of unknown genetic origin are cleaved during the process of assembly. The head of bacteriophage T4 is therefore no longer a self-assembly system in the narrow sense, because the bonding properties of the various components become altered during the assembly process.

The product of gene 23 is the principal protein component of the head of bacteriophage T4 (refs. 1–3). Two minor components of unknown genetic origin have also been found in capsids^{2,3}. Besides the product of gene 23, the products of genes 20, 21, 22, 24, 31, 40 and 66 are required to determine the size and shape of the head-shell (refs. 4 and 5 and unpublished work of F. A. Eiserling,

E. P. Geiduschek, R. H. Epstein and E. J. Metter). To several of these genes shape-specifying functions have been tentatively assigned⁵. Gene 22 is associated with the diameter selecting (initiation) process of head formation, gene 66 with the elongation of the particle and genes 20 and 40 with the formation of the hemispherical cap. Gene 31 somehow modifies or activates the major subunit for ordered assembly⁶. Ten more proteins, the products of genes 2, 4, 13, 14, 16, 17, 49, 50, 64 and 65, are thought to control later steps in head formation⁷.

Structural Components of the Phage

Many phage proteins can be separated with our improved method of disk-electrophoresis in sodium dodecyl sulphate (SDS). This system, to be described in detail elsewhere (U. K. L. and J. V. Maizel), combines the high resolution power of disk-electrophoresis⁸ with the capability of SDS to break down proteins into their individual polypeptide chains⁹. The proteins are also separated according to their molecular weight as was first reported for a continuous system¹⁰. All the proteins the genetic

Fig. 1. Autoradiogram of ^{14}C -labelled T4 phage proteins separated in acrylamide gels. ^{14}C -amino-acid-labelled preparations were analysed in 10 per cent acrylamide gels containing SDS. a, Wild type lysate; b, purified heads; c, purified phage particles; d, purified "ghosted" phage particles; e, supernatant of "ghosted" phage particles; f, "early labelled" phage particles. The prefix P is used to designate the protein of a particular gene: for example, P20 stands for the product of gene 20; the asterisk indicates that this protein is derived from a large precursor protein and has become modified during head assembly.

^{14}C -labelled lysates. Ten ml. cultures of *Escherichia coli* B^h (the restrictive host for phage carrying amber mutations) in 'M9' medium¹⁹ grown at 37°C to 2×10^8 cells/ml. were infected with the various phages at a multiplicity of five and superinfected at 8 min with the same phage and the same multiplicity to ensure lysis inhibition. Two μCi of ^{14}C -amino-acid mixture ('CFB 104', Radiochemical Centre, Amersham) with a specific activity of 45 mCi/m atom was added to each culture 13 min after the first infection. Three ml. of 3 per cent 'casamino-acids' mixture (Difco) was added to each sample at 30 min, and the infected cells were concentrated by low speed centrifugation 35 min following infection. The pellets were drained and directly resuspended in "final sample" buffer (see gel electrophoresis).

^{14}C -labelled phage and head particles. Ten ml. cultures were grown and infected as described above (^{14}C -labelled lysates). The double mutant (B255-E18) in genes 10 and 18 was used for production of tailless heads. Ten μCi of the ^{14}C -amino-acid mixture was added 13 min after the first infection to each culture. The infected cells were concentrated by a low speed centrifugation 35 min after infection and the pellet was resuspended in 1 ml. neutral phosphate buffer containing 10^{-3} M MgSO_4 , 20 μg deoxyribonuclease and a drop of chloroform. The pellet was resuspended by repeated pipetting, and incubated for 15–30 min at room temperature before layering on a CsCl step gradient²⁰. The latter was prepared in tubes for a Spinco 'SW50' rotor, with 0.8 ml. layers, and the following densities starting at the bottom of the tube: 1.55, 1.46, 1.38 and 1.29 g/cm³. Furthermore, a 10 per cent sucrose solution (in neutral phosphate buffer and 10^{-3} M MgSO_4) was layered on the last CsCl step to prevent precipitation of soluble proteins at the CsCl interface. Centrifugation was for 1 h at 40,000 r.p.m. The phage and heads, which form a sharp visible band two-thirds down the tube, were collected through the bottom of the tube and dialysed against water. The band containing the heads was always viscous, indicating that the heads lost their DNA in CsCl although the DNA was still confined within the band. Occasionally the heads lost their DNA before centrifugation particularly in more concentrated lysates, which had to be treated with deoxyribonuclease for a much longer time. "Early labelled" phages were prepared identically, but the label was added 1 min and chased 6 min after infection by the addition of 3 ml. of 3 per cent 'casamino-acids'.

"Ghosted" phage particles and supernatant of "ghosted" phage particles. Crystalline NaCl was added to ^{14}C -labelled purified phage particles in water to a final concentration of 5 M. The preparation was then repeatedly frozen in a solid CO_2 -acetone bath and thawed in warm water. This procedure releases the DNA and its internal proteins from the phage head. The sample was dialysed against neutral phosphate buffer containing 10^{-3} M MgSO_4 and the DNA digested by the addition of a small amount of crystalline deoxyribonuclease. The ghost was finally separated from the soluble proteins (internal proteins) by centrifugation and layered on a step gradient identical to that already described. Centrifugation was at 35,000 r.p.m. for 1 h. The top of the gradient containing the internal proteins was collected with a pipette and the ghosts, which band at an approximate density of 1.3 g/cm³, were collected through the bottom of the tube. SDS at a final concentration of 2 per cent was added to both samples and the samples were dialysed against water containing 2 per cent SDS.

Gel electrophoresis. Gels containing 3 per cent (stacking gel), 8.0 per cent or 10 per cent acrylamide were prepared from a stock solution of 30 per cent by weight of acrylamide and 0.8 per cent by weight of N,N'-bis-methylene acrylamide. The final concentrations in the separation gel were as follows: 0.375 M Tris-HCl (pH 8.8) and 0.1 per cent SDS. The gels were polymerized chemically by the addition of 0.025 per cent by volume of tetramethylethylenediamine (TEMED) and ammonium persulphate. Ten cm gels were prepared in glass tubes of a total length of 15 cm and with an inside diameter of 6 mm. The stacking gels of 3 per cent acrylamide and a length of 1 cm contained 0.125 M Tris-HCl (pH 6.8) and 0.1 per cent SDS and were polymerized chemically in the same way as for the separating gel. The electrode buffer (pH 8.3) contained 0.025 M Tris and 0.192 M glycine and 0.1 per cent SDS. The samples (0.2–0.3 ml.) contained the final concentrations ("final sample buffer"): 0.0625 M Tris-HCl (pH 6.8), 2 per cent SDS, 10 per cent glycerol, 5 per cent 2-mercaptoethanol and 0.001 per cent bromophenol blue as the dye. The proteins were completely dissociated by immersing the samples for 1.5 min in boiling water²¹. Electrophoresis was carried out with a current of 3 mA per gel until the bromophenol blue marker reached the bottom of the gel (about 7 h). The proteins were fixed in the gel with 50 per cent trichloroacetic acid (TCA) overnight, stained for 1 h at 37°C with a 0.1 per cent Coomassie brilliant blue solution made up freshly in 50 per cent TCA. The gels were diffusion-destained by repeated washing in 7 per cent acetic acid. Autoradiograms of gels were prepared by a modified version (U. K. L. and J. V. Maizel, unpublished) of Fairbanks *et al.*²² (autoradiograms are shown in Figs. 1–7).

origin of which was determined are labelled in Fig. 1, and their molecular weights are listed in Table 1. At least 28 bands can be distinguished in the autoradiogram of radioactively labelled, purified phage particles (Fig. 1c). The 28 proteins found in dissociated phage particles do not include proteins with molecular weights less than about 15,000. Those proteins are not sieved in gels of 10 per cent acrylamide (unpublished results of U. K. L. and J. V. Maizel) and migrate with the marker dye. In gels of higher acrylamide concentration another three low molecular weight proteins have been separated (results not shown). The largest protein in the phage has an approximate molecular weight of at least 120,000 and no label stays at the top of the gel, indicating complete dissociation of the particles by the method used.

Eleven of these 28 proteins are found in the purified head preparation (Fig. 1b). The remaining 17 proteins absent from the head but present in the whole phage pattern are presumably structural proteins of the tail and tail fibres. The complete absence of these proteins from the head gel pattern indicates the high degree of purity of the preparation. The classification of the proteins into tail and head components may not be valid for proteins making up the head to tail junction.

Only two minor proteins besides the major components P23 were found by others^{2,3} in phage capsids purified in the same way but fractionated in urea gels. The larger number of proteins found in SDS gels is to be expected, for at least 46 genes are known to affect T4 morphogenesis^{4,7} although the proteins of these genes may not all be incorporated into the particle.

The gel pattern of a total lysate of wild type infected cells radioactively labelled at late times is presented in Fig. 1a. Note that most of the resolved proteins that

are synthesized late in infection are structural phage components. A few rather intense bands (X_1 and X_2), however, are completely missing in the phage particles, also demonstrating that the separation of the phage particles from the soluble proteins is complete.

When phages are subjected to osmotic shock a number of proteins are released¹¹. The principal one is IP*, an internal protein (Fig. 1). It is present in complete phage particles, is extracted from the phage particles by freezing and thawing in high salt concentrations and is quantitatively recovered in the supernatant. The supernatant fraction also contains many minor components which are found both in phages as well as phage ghosts, indicating that the

Table 1. MOLECULAR WEIGHTS OF PHAGE PROTEINS DETERMINED BY COMPARING THEIR MOBILITY IN SDS GELS WITH THOSE OF MARKER PROTEINS WITH KNOWN MOLECULAR WEIGHTS^{10,22}

Gene product	Observed value in SDS gels	Published value
P18	69,000	50,000 ⁸
P20	63,000	
P23	56,000	
P23*	46,500	46,000 ²¹
P24	45,000	
P24*	43,500	
P22	31,000	
IP	23,500	
IP*	21,000	
P19	18,000	

The following marker proteins were used: serum albumin (68,000), γ -globulin, heavy chain (50,000), ovalbumin (43,000), γ -globulin, light chain (23,500) and TMV (17,000), to calibrate 10 per cent acrylamide gels. In this improved gel system the distances of migration of the various marker proteins relative to the distance of migration of bromophenol blue are also a linear function of the logarithm of the molecular weight of the marker proteins, as has been described^{10,22}. Radioactively labelled phage proteins were mixed with unlabelled marker proteins before electrophoresis; the distance of migration of the phage proteins was determined from the autoradiogram and those of the marker proteins from the stained gel. It is assumed that the phage proteins also separate in SDS gels solely according to their molecular weight.

Fig. 2. Identification of gene products on 10 per cent acrylamide gels. The lysates were prepared as described in Fig. 1 and analysed on 10 per cent acrylamide gels. *a*, Gene 20-defective lysate, mutant N50; *b*, gene 21-defective lysate, mutant N90; *c*, gene 22-defective lysate, mutant B270; *d*, gene 23-defective lysate, mutant H11; *e*, gene 31-defective lysate, mutant N54; *f*, gene 24-defective lysate, mutant N65; *g*, lysate from wild type infected cell; *h*, gene 18-defective lysate, mutant E18; *i*, gene 19-defective lysate, mutant E1137. Mutants N90 (gene 21), E18 (gene 18) and E1137 (gene 19) carried second mutations in gene 10 (mutant B255). The following amber fragments may be detected. A rather intense band just below P23 is consistently seen in 18-defective lysates, and is presumed to be the amber fragment of mutant E18 in gene 18. Furthermore, the gel pattern of defective lysates of all double mutants in genes 18-10, 21-10, and 19-10 possess a band just above P23 which is probably the amber fragment of mutant B255 in gene 10. It is striking that the amber fragment of mutant B270 gene 22 behaves anomalously in the gel: it migrates more slowly than the wild type product, although SDS gels are known to separate on the basis of molecular weights. This anomalous behaviour of certain proteins will be discussed elsewhere (U. K. L. and J. V. Maizel).

separation of the released proteins and the ghosted particles by centrifugation was not complete. Some of these proteins, however, are extracted into the supernatant quantitatively by the freezing and thawing procedure.

Only the protein IP*, and perhaps some low molecular weight proteins which migrate with the marker dye, are structural phage components synthesized at early times (early proteins). This can be seen in the gel pattern of purified phage labelled at early times only (Fig. 1*f*). IP* is also labelled at late times. All the other structural phage components are synthesized only late in infection. Some of the principal late proteins show up on the autoradiogram, probably because of residual incorporation of radioactive amino-acids following the chase with unlabelled amino-acids.

Identification of Gene Products

The products of genes 18, 19, 20, 22, 23 and 24 were identified by comparing the gel pattern of extracts of cells infected with wild type phage with those infected with amber mutants in various genes. The identification of the tail and tail fibre proteins will be described later (J. King and U. K. L.). Amber mutations produce only fragments of the protein chain of the mutant gene on infection of restrictive bacteria¹. These fragments migrate differently in the gel from the complete proteins. The molecular weights of the proteins identified are listed in Table 1. Fig. 2 is the autoradiogram from dried and sliced gels for

various mutants. The product of gene 20 is identified by its absence in the gel pattern of a 20-defective* lysate (Figs. 2 and 3*a*), and the product of gene 22 by its absence in the gel pattern of a 22-defective lysate (Figs. 2 and 3*c*). Note the amber fragment of mutant B270 in gene 22. This fragment was also identified by Hosoda and Levinthal¹³ in urea gels (see legend to Fig. 2).

The product of gene 23 is easily identified by its absence in the gel pattern of a 23-defective lysate (Fig. 2*d*). It can also be seen that P23 overlaps with two minor tail components. If the 23-defective lysate is analysed on gels of lower acrylamide concentration another important observation is made. A band, P23*, which is detected in variable amounts in the other head defective lysates, is completely missing in the 23-defective lysate (Fig. 3*d*). This band, P23*, overlaps with P24 in Fig. 2, but is better separated from P24 in less concentrated gels (Fig. 3). As with the product P23, the product of P24 was identified by its absence in the gel pattern of a 24-defective lysate (Figs. 2*f* and 3*e*).

So far, no missing bands have been found in the gel patterns of 31 or 21-defective lysates (Fig. 2*b* and *e*), but analysis of the 21-defective lysate on gels of lower acrylamide concentration (Fig. 3*b*), which resolves higher molecular weight proteins better, clearly shows that a band is missing. This protein, however, is the product of gene 10, a baseplate gene. The mutant N90 in gene 21 in fact carries a second mutation in gene 10 (mutant B255).

In comparing the gel pattern of the head-defective lysates (Fig. 2*a-f*) with that of wild type (Fig. 2*g*), further important differences are observed, which shed light on the precursor-product relationship of the head components.

The principal fraction of the gene 23 product has a molecular weight of 56,000 in all the head-defective lysates, but in wild type or tail-defective lysates it appears at the position of P23*, with a molecular weight of 46,500. Small but significant amounts of P23* are also observed in head-defective lysates (Fig. 3*a-f*). In lysates prepared identically about 20 per cent of the total P23 is converted to P23* in the 20-defective lysate, 10 per cent in 21 and 2-3 per cent in 22, 24 and 31-defective lysates, as determined from densitometer tracing of the autoradiographs.

The bands P22 and IP are both absent or considerably less intense in the wild type gel pattern (each overlaps with two other proteins). A new band, IP*, is seen at the bottom of the gel, which is completely missing in the head defective lysates (Fig. 2*a-f*).

The band P24, which is found in all head-defective lysates is missing in the wild type pattern, but a new band, P24*, which migrates slightly faster is observed. This is difficult to visualize in Fig. 2, but will become evident in Fig. 6.

Also included in Fig. 2 is the gel pattern of two tail defective lysates. The product of gene 18 (mol. wt 69,000), the principal protein of the tail sheath¹³, is identified by its absence in an 18-defective lysate (Fig. 2*h*) and the product of gene 19 (mol. wt 18,000) by its absence in a 19-defective lysate (Fig. 2*i*). P19 is thought to be the chief component of the tail tube¹⁴. This demonstrates that the differences in the head proteins are not related to tail attachment, for the gel patterns of the tail-defective lysates are identical with that of wild type.

Evidence will be presented that the proteins P23, P22, P24 and IP are cleaved in wild type infected cells and are precursors to proteins P23*, P24* and IP* found in the final head structure. (The cleavage product of P22 was not detected.) This precursor-product conversion is strongly inhibited by mutations in genes 20, 21, 22, 23, 24 and 31. Two important conclusions can be drawn: (a) the aberrant head-related structures—single and

* Henceforth, lysates of cells infected at restrictive conditions with amber mutants in various genes will be referred to as, for instance, a "21-defective lysate", where the amber mutant used was in gene 21.

multi-layered polyheads^{4,5,15}, τ -particles^{4,5,16} and lumps⁶ known to be produced in these mutant infected cells—chiefly consist of the precursor protein P23; (b) because P22 is not cleaved in these mutant infected cells, but is required for polyhead and τ -particle formation, as has been established by genetic means⁵, it is strongly suggested that P22 is incorporated into these structures as such.

Kinetics of the Cleavage Reactions

The following experiments were designed to study the precursor relationship of the proteins P23, P24 and IP with P23*, P24* and IP*, respectively. In this experiment the infected cells were pulse-labelled with radioactive amino-acids for a short period (1 min) and the modification of the various proteins was then followed by analysis of the samples taken at intervals in SDS gels. The results of autoradiography of the dried gels are presented in Fig. 4.

Cleavage of P23. It is readily seen in Fig. 4 that most of the 23 protein is at the position of P23 immediately following the pulse of the radioactive amino-acids. It then rapidly disappears, and a new band, P23*, appears simultaneously. That P23 is cleaved and gives rise to P23* is suggested by the fact that both are principal components and this is reinforced by the absence of P23 and P23* from the gel patterns of a 23 defective lysate (Fig. 3d). The kinetics of the cleavage reaction P23→P23* are plotted in Fig. 5a. Cleavage is very rapid: about 50 per cent of the precursor is cleaved within the first 2 min following chase of the label. P23* appears at about the same rate, in a satisfactorily correlated way. The total labelled protein in P23 and P23* is also plotted in Fig. 5a. The total label increases during the first minute, which reflects the completion time of the chase of the labelled amino-acid, but finally the total falls off by 25–30 per cent. This final decrease of the total labelled protein can be nicely explained, for a cleavage from about 56,000 to 46,500 corresponds to a loss of about 20 per cent by weight of protein.

Cleavage of P22 and IP. In the pulse-chase experiment of Fig. 4, two other protein bands, P22 and IP, disappear with time. (The disappearance of P22 in wild type infected cells

Fig. 3. Identification of gene products on 8 per cent acrylamide gels. ¹⁴C-labelled lysates were prepared as described (Fig. 1) and analysed on 8 per cent acrylamide gels. a, Gene 20-defective lysate, mutant N50; b, gene 21-defective lysate, mutant N90; c, gene 22-defective lysate, mutant B270; d, gene 23-defective lysate, mutant H11; e, gene 24-defective lysate, mutant N65; f, gene 31-defective lysate, mutant N54.

Fig. 4. Cleavage of products of genes 22, 23, 24 and protein IP (10 per cent acrylamide gels). A 10 ml. culture grown at 37° C was infected with a double mutant defective in genes 10 and 18 (mutant B255 and E18) as described (Fig. 1). The radioactive amino-acid mixture (10 μ Ci) was added 14 min after the first infection, and chased 1 min later with an excess of unlabelled amino-acids (final concentration 1 per cent). The chase of the label was verified by measuring the counts in the total TCA precipitable proteins. One ml. samples were prepared at intervals after the chase and immediately frozen in a solid CO₂-acetone bath. SDS was added after thawing to a final concentration of 2 per cent and the samples were carefully dialysed into 2 per cent SDS in water. The samples were finally mixed with an equal volume of twice concentrated "final sample buffer" and boiled for 1 min before electrophoresis. The sampling time is indicated at the bottom of the gels. All the preliminary experiments were done with wild type phage, but this experiment was performed with the double mutant in genes 10 and 18 in view of plans for future experiments.

has also been observed by M. Showe, personal communication.) A new band, IP*, appears at the bottom of the gel pattern. The kinetics of these cleavage reactions are plotted in Fig. 5b. P22 disappears with approximately the same initial rate as P23: about 50 per cent is cleaved 2–3 min following chase of the labelled amino-acids. I have not found a band in the gel pattern which may be derived from P22. Hosoda and Levinthal¹² reported indirect evidence that P22 is a structural phage component, but they considered the possibility that P22 might become altered during head formation.

Evidence for the precursor-product conversion IP→IP* is provided by the observation that the disappearance of IP and the appearance of IP* is coordinated in time (Fig. 5b). Furthermore, the total label lost at the IP position is recovered in the IP* band. The reaction is slower than that of P23 and P22. Only about 50 per cent of the total label at the IP position disappears. This could be explained either by another protein band overlapping with the IP band or synthesis in excess.

IP* cannot arise from P22. IP* must be derived from a precursor which is synthesized early, for I have shown (Fig. 1) that IP* is strongly labelled in the "early labelled" phage preparation. P22, however, is reported to be synthesized at late times only¹², which I have confirmed. The precursor conversion of IP→IP* has also been observed in a pulse-chase experiment in which the label was added between 4 and 5 min following infection, thus labelling only early proteins (results not shown). The band IP was easily recognized in these gels and the disappearance of IP and the appearance of IP* were again correlated in time. This quantitative agreement and the absence of other unaccounted changing bands in the gel pattern support the argument for the IP→IP* relationship. Of course, a final proof awaits chemical analysis.

It was also observed that, although the pulse was performed between 4 and 5 min after infection, cleavage of IP starts only

Fig. 5. Kinetics of cleavage of P23, P22 and IP. The kinetics of cleavage were measured using a microdensitometer (double beam recording microdensitometer, Joyce-Loebl) to record the autoradiogram. The exposure of the autoradiogram was chosen so that the absorbance of the band to be measured did not exceed 1 unit. The abscissa represents the integrated absorbance over the relevant peaks. *a*: ●—●, integrated absorbance over the P23* peak; □—□, integrated absorbance over the P22* peak; ○—○, total absorbance in P23 and P22*. *b*: ▲—▲, integrated absorbance over peak IP; ●—●, integrated absorbance over peak P23; ○—○, integrated absorbance over peak P22.

at late times (after 17 min). Phage assembly starts at about this time and it is therefore thought that the cleavage of IP is linked to phage assembly.

Cleavage of P24. P24* (mol. wt 43,500) appears coordinately with P23* and P22* (Fig. 4) (the kinetics are not plotted). The precursor product relationship $P24 \rightarrow P24^*$ is more difficult to demonstrate, because P24 migrates only slightly faster than P23*, but the following experiment proves that P24 is missing in a pulse-chase wild type lysate. P24 separates somewhat better from P23* in a gel of lower concentration. The samples of the pulse-chase experiment were analysed on 8 per cent acrylamide gels and four time points are presented in Fig. 6. P24 is easily distinguished from the small amount of P23* existing immediately after the chase of the radioactive label (Fig. 6, 15 min). P24 disappears at the same time as P24* appears while P23* increases. One might argue that P24 is obscured by the heavy P23* band. This possibility was excluded by adding a lysate (23-defective lysate) containing P24 to the final samples of the pulse-chase experiment. P24 was then detected and it can be concluded that measurements of P24 are reliable, thus showing that P24 most likely gives rise to P24*. The integrated absorbance values over these two bands are about equal, but the small loss of protein weight by the $P24 \rightarrow P24^*$ reaction is not likely to be detected by the densitometric measurements. P24 could not give rise to IP*, because the total label in IP* is two or three times larger than that of P24 and P24 is synthesized late. Moreover, the precursor relationship of $P24 \rightarrow P24^*$ is considerably strengthened by recent observations on head maturation genes (my unpublished results). P24 does not seem to be cleaved at all in 50-

defective cells and, indeed, no P24* is found. Cleavage of P23, P22 and IP does occur in 50-defective cells, although at a reduced rate.

Fate of the Small Fragments

Where are the small fragments of these cleavage reactions? The expected molecular weights for the small fragments stemming from P23, IP and P24 would be about 10,000, 2,500 and 1,500 respectively. Peptides of this size are not sieved on 10 per cent acrylamide gels and migrate with the marker dye (unpublished results of U. K. L. and J. V. Maizel). Attempts to find at least the 10,000 molecular weight fragment from P23 on gels of higher acrylamide concentration have failed. Possibly the fragments are further broken down to undetectable sizes. Fragments of P22 also have not been detected. Acid-soluble components which are derived from an acid-insoluble precursor are known to exist in T4 infected cells¹⁷. Two are associated with the phage particle and they are released with the DNA from the head upon osmotic shock¹⁷. The genetic determinant of one of these internal peptides has been mapped recently and lies in the neighbourhood of genes 20 and 21 (ref. 18). My results definitely rule out gene 20, which is incorporated unmodified into normal phage. Unfortunately, I have not discovered the product of gene 21 in the gel pattern. These results do not rule out the possibility that one of the internal proteins is derived from the small cleavage fragment of P22, P23 or P24. The appearance of the internal peptides seems indeed to be coordinated with the cleavage reactions of P23, P22 and P24. Genes 20, 21, 22, 23, 24 and 31, which affect the cleavage of P23, P22 and IP, are known also to affect the appearance of the internal peptides¹⁷.

It has been pointed out to me by S. Brenner and A. Stretton that the cleavage point must occur at the N-terminal end of the P23 protein. In establishing the co-linearity of gene 23 and its polypeptide⁴, they observed peptides in 23-defective lysates which contain the amber fragments, but these are absent in wild type lysates or in purified phage particles. These peptides may be derived from the N-terminal end of the amber fragment, which is cleaved off in the protein P23*. These observations also suggest that the small cleavage fragment, with an expected molecular weight of about 10,000, is fragmented to even smaller pieces.

Fig. 6. Cleavage of the product of gene 24 (8 per cent acrylamide gels). Some samples (15, 16, 19 and 26 min) of the pulse chase experiment of Fig. 4 were analysed on 8 per cent acrylamide gels. Only the relevant part of the gel pattern is shown.

Cleavage occurs in a Large Structure

The observation that all the proteins P20, P21, P22, P23, P24 and P31 are required for efficient cleavage of P23, P22, P24 and IP suggests that these precursor proteins aggregate first to form an oligomeric structure, and are cleaved subsequently, rather than being cleaved first, and then assembled. The following experiment supports this view. The experiment is based on the observation that most of the precursor proteins are soluble and monomeric in SDS at room temperature, but that phage particles are not totally disrupted, as is also true in urea¹². The gel pattern of purified phage treated with SDS at room temperature is compared with completely degraded phage, boiled for 1 min in SDS (Fig. 7a and b). Only a small fraction of P23* is extracted from phage with SDS at room temperature. Most of the proteins stay at the top of the gel or enter the gel as high molecular weight aggregates. Some proteins are not extracted at all. Note, however, that a few proteins are almost quantitatively extracted from the phage particles. The samples from the pulse-chase experiment treated in SDS at room temperature only are shown in Fig. 7. P23 disappears with time but no P23* appears, suggesting that P23 enters an SDS-resistant structure before being cleaved. Of course, these experiments cannot rule out the possibility that P23* is converted to an SDS-resistant structure so rapidly that it is not detected. A high molecular weight protein appeared at the top of the gel, which could be an aggregate of P23 but only accounts for part of the label which disappears from P23. Most of the label stays at the top of the gel. The molecular weight of this structure must therefore be greater than 300,000, for such a molecular weight is excluded from these gels (unpublished results of U. K. L. and J. V. Maizel). It is possible that this structure has a capsid-like shape. IP* and P24* are not resolved in these gels. This is because of the high salt concentration in these samples ('M9' growth medium) which impairs the resolution of the gel in the low molecular weight region.

Maturation of the Head

My experiments demonstrate that the assembly of the head of bacteriophage T4 is not a simple, straightforward self-assembly, because several structural proteins are chemically altered at some stage of assembly. The uncleaved precursor protein P23 can, however, be polymerized into single and multilayered polyheads and τ -particles, if its cleavage is blocked as a result of mutation.

Investigations of genes 2, 4, 13, 14, 16, 17, 49, 50, 64 and 65, which supposedly control late steps in head formation, are in progress. It is interesting that the cleavage of P23, P22, P24 and IP seems to be normal in cells infected with phage carrying mutations in these genes with the exception of genes 2, 50 and 64 (my unpublished results).

Why are these structural head components cleaved? The finding that IP gives rise to an internal IP* sheds light on a possible consequence of the cleavage reactions. Internal proteins are thought to bind to DNA and the cleavage reactions may possibly trigger the necessary DNA-protein interactions, which result in orderly packing of the DNA within the shell of proteins. The following model may be proposed. The proteins P20, P21, P23, P24, P31 and IP form an intermediate structure (SDS-resistant) which combines with an end of a DNA strand. Cleavage of P23, P22, P24 and IP proceeds from the DNA attachment site. During this process more and more DNA binding sites may be formed at the inside of this structure, perhaps by the formation of IP*, thus winding up the DNA strand successively. The small acid-soluble peptides formed during this process may also interact with the packed DNA¹⁷ to neutralize charges. My results do not decide whether DNA packing proceeds simultaneously with the polymerization of the head membrane or follows thereafter.

I thank Dr A. Klug for encouragement and facilities, my colleagues J. King, J. Maizel and S. Altman for many valuable suggestions (J. Maizel in particular for advice on gel techniques and J. King for help in preparing the manuscript), and S. Brenner (among others) for critically reading the manuscript. U. K. L. holds an EMBO fellowship.

Fig. 7. Chase of P23 into a product stable to SDS at room temperature. A culture was infected and pulse labelled as described in Figs. 1 and 3 with the following changes. The culture was grown at 30° C, infected with wild phage, and labelled for 2 min from 15–17 min after infection. The samples were mixed at room temperature with an equal volume of twice concentrated "final sample buffer" without previous dialysis. The samples were then directly applied to the gels without being boiled. The sampling time is indicated at the bottom of the gels. As a control a purified phage preparation is analysed. a, Phage treated in SDS at room temperature only; b, phage boiled in SDS for 1.5 min.

Note added in proof. During the preparation of this manuscript I was informed that the alteration of P23 has also been observed by other workers: E. Kellenberger and C. Kellenberger-van der Kamp, *FEBS Lett.*, **8**, 3, 140 (1970); R. C. Dickson, S. L. Barnes and F. A. Eiserling, *J. Mol. Biol.* (in the press); and J. Hosoda and R. Cone, *Proc. US Nat. Acad. Sci.* (in the press).

Simultaneous Acquisition of Metamorphic Response and Hormone Binding in *Xenopus* Larvae

by

J. R. TATA

National Institute for Medical Research,
Mill Hill, London NW7

The acquisition of early metamorphic competence (36–60 h after fertilization) of developing *Xenopus* larvae is accompanied by the appearance of strong, temperature-sensitive binding sites for thyroid hormones. The findings have general relevance to the study of hormone "receptors".

RECENT work on the sequential binding of steroid hormones to cytoplasmic and nuclear proteins has revealed the existence of highly specific mechanisms of hormone recognition in their respective target tissues^{1,2}. These studies, which are based on the detection by radioactive hormone tagging of hormone "receptors" present in minute amounts, but with a high binding affinity, pose two major questions about the role of such binding in the biological action of the hormone. Can the interaction of the hormone with the truly relevant "receptor" sites, that is those that are an integral part of the initiation of hormone action, be distinguished from those that are not, such as those that may "buffer" the tissue against an excess or loss of the hormone? Second, is there a relationship between the binding and action of the hormone? While the answer to the first question must await the development of radically new techniques, the second question may be approached by a combination of indirect observations. For example, with steroid hormones it has been shown that the binding to cytoplasmic and nuclear components is abolished by compounds with strong anti-hormone properties^{3,4}. Another valuable approach in this direction, and one which has not yet been exploited, may be a developmental one. I describe here initial studies on hormone-binding during the early developmental stages of *Xenopus* larvae which reveal that whole embryos acquire an intense capacity to bind thyroid hormones at the same time as an early metamorphic competence as judged by biochemical responses of the organism to these hormones.

Earlier observations⁴ have shown that the developing larva of the clawed South African toad, *Xenopus laevis*, is unresponsive to the obligatorily metamorphic hormones, L-thyroxine (T_4) and 3,3',5-triiodo-L-thyronine (T_3), for about 40–60 h after fertilization. After this period the larva acquires competence in that it now responds to the hormone in a very abrupt fashion. Competence of response has been assessed in a number of biochemically ways such as changes in rates of synthesis of nucleic acids, proteins and phospholipids, PO_4^{3-} uptake, hydrolase induction, or—after a longer period—morphological changes characteristic of normal metamorphosis. I decided to follow the capacity and nature of thyroid hormone binding before and after the acquisition of metamorphic competence. There is virtually no type of cell in the pre-metamorphic tadpole that does not respond directly to thyroid hormones^{5,6}, and I therefore first attempted to study the larva as a whole. Furthermore, I have assumed that the diversity of biochemical and morphological responses of different cell types arises from the diversity of their commitments for further development by partially differentiated cells rather than from a diversity in the types of "receptors" or binding components.

The experimental design was based on the demonstration of acquisition of competence to respond to thyroid hormone by developing *Xenopus* larvae⁴. All conditions for ovulation, fertilization, growth and feeding of larvae were the same as described earlier⁴. Fig. 1 depicts a typical experiment in which binding of trace amounts of ^{125}I - T_3 was measured in *Xenopus* embryos at different stages of development. There was a marked increase in the affinity for the hormone of the developing organism between 40 and 60 h after fertilization (Nieuwkoop–Faber stages 34–41).

The increase in binding was most noticeable when expressed per embryo although quite substantial in terms of mg wet weight. The stages 36–41 of development are those stages which have been earlier characterized as the period of acquisition of sensitivity of the embryos towards thyroid hormones⁴. At all stages of early development the uptake of radioactive T_3 proceeds in a linear fashion for nearly 2 h at 20°.

In the next series of experiments the total capacity (as opposed to affinity) of the larvae to fix the hormone and its derivatives was determined by measuring the uptake of the radioactivity in the presence of increasing amounts of the non-radioactive compound. It was thus found that for both T_4 and T_3 the binding capacity increased rather abruptly and continued to do so for a period of time (Fig. 2). The binding capacity of the larvae increased from about 2 nmoles of T_4 /mg larval protein at 1 day after fertilization to over 25 nmoles and 45 nmoles at 3 and 6 days, respectively. The binding capacity for T_3 (Fig. 3) and T_4 (not shown in Fig. 3) exhibited a linear dependence on the amount of larval protein at all stages of larval development. During the early period of develop-

Fig. 1. Binding of a tracer (8×10^{-9} M) amount of ^{125}I - T_3 by *Xenopus* larvae at different stages of development (expressed as time after fertilization). Except for the one-day stage, a total of 200 mg of washed larvae was put in 50 ml. of water containing 8 μ Ci of ^{125}I - T_3 (0.4 nmoles) for different periods of time at 20° C. 500 mg of one-day embryos was used to allow for the large amount of jelly still present at this stage. At the end of different times of incubation the larvae were processed for bound ^{125}I - T_3 determinations. The larvae at different stages of fertilization were carefully washed in distilled water, and a variable number but a fixed weight of animals (200–500 mg) exposed to ^{125}I or ^{131}I -labelled T_4 , T_3 , or their analogues, for different times at controlled temperatures. The ^{125}I -labelled hormones were purchased from the Radiochemical Centre, Amersham; the ^{131}I -labelled compounds were prepared by radiolodination. Glassware was replaced with teflon or polypropylene apparatus for the pipetting and handling of the radioactive hormones because of the high affinity of glass for the hormones⁷. The binding of radioactive hormone was assessed by five quick washes of the larvae with water containing 10^{-4} M KI and homogenizing them in a teflon disintegrator with 1–5 ml. of 0.15 M NaCl. The radioactivity was determined in a Packard 'Autogamma' well-type scintillation spectrometer. In some experiments, ^{131}I was also measured in the homogenate, the 105,000g sediment and supernatants, as well as in the precipitate and supernatant obtained after treatment and washing of the larval homogenate with 5 per cent trichloroacetic acid. The larvae at each stage of development were obtained from different batches of eggs fertilized at different intervals of time so that the experiment was performed at the same time. Stages of development: ○, 1 day; △, 2 days; □, 2.5 days; ■, 3 days; ▲, 5 days after fertilization.

ment the larval protein and DNA content change in different ways. In the first 2-3 days after fertilization there is a very rapid increase in DNA content of the larva, followed by a more gradual change. On the other hand, the protein content dropped initially because of resorption of yolk and surrounding jelly but increased quite rapidly after 3-4 days, that is, following the feeding stage of the larvae. Thus, the pattern of increase in hormone binding capacity varies according to whether the results are expressed per unit protein or DNA (Fig. 4). It seems that initially the appearance of additional binding sites is a function of appearance of new cell population followed by an increase geared to the overall accumulation of proteins.

The binding is specific with respect to the biological activity of the analogue used as shown in Table 1. Thus the biologically more active analogues^{5,8}, T_3 and its propionic acid analogue were more avidly bound than the inactive analogues, 3,5-diiodo-L-thyronine and 3,5-diiodo-L-tyrosine. There was only a relatively small difference in binding affinities of the different compounds at 1.5 days after fertilization, but the difference between the biologically active and inactive analogues became more

Fig. 2. Capacity to bind ^{125}I -labelled T_4 (□) and T_3 (Δ) by *Xenopus* larvae obtained at 1 (—), 3 (---) and 6 (— · —) days after fertilization. 500 mg of 1-day embryos and 225 mg of 3 day and 6 day stages were kept in 20 ml. of water containing $10\ \mu\text{Ci}$ of either hormone along with the different amounts of non-radioactive hormone, as indicated. The larvae were exposed to radioactive hormones for 40 min at 20°C . All other details as in Fig. 1.

Fig. 3. Dependence of hormone binding capacity on the amount of larval protein. One (○), 3 (Δ) and 6 (□) day old larvae in different amounts were immersed in 30 ml. of water containing $2 \times 10^{-4}\ \text{M}$ ^{125}I - T_3 ($10\ \mu\text{Ci}$) for 45 min at 19°C .

Fig. 4. Increase in T_3 binding capacity, expressed either per mg protein (●) or DNA (○) in larvae obtained at different times after fertilization. 450 mg of larvae at the one-day stage and 200-270 mg at other stages were kept for 40 min in water containing $2 \times 10^{-4}\ \text{M}$ T_3 ($8\ \mu\text{Ci}$) at 20°C .

apparent at 3.5 days. In saturation experiments, I found that the binding capacity was highest for T_4 , as is the case for mammalian blood and tissue proteins^{7,8}. Another type of experiment which also revealed chemical specificity of hormone-binding was competition by a large excess of unlabelled analogue added at the same time as the labelled hormone (see Table 2). The labelled hormone could only be displaced from the larval binding sites by analogues which are known to have high metamorphosis-inducing activity^{5,9}. Similar results in the binding of steroid hormones to their target tissues^{1,2} have been interpreted to reflect physiological relevance of the binding process.

In analysing the time-course of T_4 binding to larvae of different ages, I found that even very young larvae showed a substantial capacity to bind the hormone before they reached the stage when competence to respond to the hormone is reached⁴. It was thus necessary to decide whether this represented a non-specific absorption of hormone to sites present at all stages of development, or binding to physiologically relevant binding sites that may appear only at the time the organism shows a response to the hormone. While no direct and conclusive experiment could be designed to answer this question, I decided

Table 1. RELATIVE BINDING AFFINITIES OF *Xenopus* LARVAE FOR T_4 AND ITS BIOLOGICALLY ACTIVE AND INACTIVE ANALOGUES

Analogue	Potency ^{5,9}	Developmental stage (days)	Analogue bound (μmoles/mg)
L-Thyroxine (T_4)	High	1.5	240
		3.5	895
D-Thyroxine	Slight	1.5	332
		3.5	407
3,3',5-Triiodo-L-thyronine (T_3)	High	1.5	133
		3.5	769
3,3',5-Triiodothyropropionic acid	Very high	1.5	187
		3.5	1,463
3,5-Diiodo-L-thyronine	None	1.5	68
		3.5	135
3,5-Diiodo-L-tyrosine	None	1.5	98
		3.5	65

Larvae obtained at 1.5 and 3.5 days after fertilization were immersed in 20 ml. of water containing $5\ \mu\text{Ci}$ of labelled L-thyroxine or analogue ($5 \times 10^{-7}\ \text{M}$) for 10 min at 21°C . T_4 and T_3 were labelled with ^{125}I and the other analogues with ^{131}I .

Table 2. DISPLACEMENT OF LABELLED ^{125}I - T_4 BOUND TO *Xenopus* LARVAE BY BIOLOGICALLY ACTIVE AND INACTIVE ANALOGUES

Unlabelled analogue added	Concentration (M)	^{125}I - T_4 bound (c.p.m./mg)
None	—	2,355
L-Thyroxine (T_4)	8.0×10^{-7}	1,440
	5.2×10^{-6}	165
3,3',5-Triiodo-L-thyronine (T_3)	5.0×10^{-7}	804
	3.2×10^{-6}	249
D-Thyroxine	8.0×10^{-5}	1,085
3,3',5-Triiodothyropropionic acid	5.0×10^{-7}	1,160
	3.4×10^{-7}	311
3,5-Diiodo-L-thyronine	6.0×10^{-6}	1,980
3,5-Diiodo-L-tyrosine	2.5×10^{-4}	2,208

250-350 mg of 4.5 day old larvae were immersed in 30 ml. of water containing $20\ \mu\text{Ci}$ of tracer ^{125}I - T_4 ($6 \times 10^{-9}\ \text{M}$) and the non-radioactive analogue, at the concentrations indicated for 45 min at 18°C .

Fig. 5. Correlation between the appearance of temperature-sensitive binding capacity for T_3 (●) and the acquisition of a metamorphic response to thyroid hormone by developing *Xenopus* larvae. The temperature-sensitive binding component(s) was calculated by subtracting the binding capacity for T_3 at 25°C from that expressed at 5°C , as described in Table 3 and Fig. 4. The metamorphic response to T_3 is illustrated for the increase in the rate of RNA synthesis (Δ) or the diminution of uptake of PO_4^{3-} ions (\circ) when *Xenopus* larvae at different stages of development are exposed to $10^{-9}\text{ M } T_3$. The data on the early metamorphic response are taken from an earlier work⁴.

to exploit a difference in temperature sensitivity of binding at different stages of development which was initially observed by chance. Table 3 shows that whereas the hormone binding capacity at very early stages (before stage 30) was only slightly affected when measured at 5°C and 25°C , there was a marked increase in binding at the higher temperature in larvae beyond stages 36–40. It seems, therefore, that the acquisition of metamorphic competence is accompanied by the appearance of a temperature-sensitive T_3 -binding component. It is interesting that bullfrog tadpoles have been shown to exhibit temperature sensitivity during hormone-induced metamorphosis¹⁰, although it is difficult to establish a direct relationship between these two phenomena.

Assuming that the temperature-sensitive hormone-binding component(s) is related to metamorphic response, corrections were made for temperature in binding experiments shown in Figs. 1 and 2 and plotted against the known time-course of biochemical response of the developing larvae, derived from earlier work⁴. As shown in Fig. 5, there is a very good fit between temperature-sensitive hormone binding and the onset of metamorphic competence as judged by two biochemical indices (increase in the rate of RNA synthesis and decrease in PO_4^{3-} uptake). As the embryo developed, the correlation between bio-

Table 3. TEMPERATURE SENSITIVITY OF BINDING OF T_3 BY *XENOPUS* LARVAE BEFORE AND AFTER ACQUIRING METAMORPHIC COMPETENCE

Developmental stage (days)	Temperature ($^\circ\text{C}$)	$^{125}\text{I}-T_3$ bound (c.p.m./mg)
1.0	5	89
	15	125
	25	110
2.5	5	163
	15	295
	25	370
4.5	5	350
	15	879
	25	1,065
7.0	5	471
	15	1,208
	25	1,835

200–500 mg of larvae at different developmental stages were equilibrated at the different temperatures in 2.0 ml. of water for 30 min, following which $10\text{ }\mu\text{Ci}$ of $^{125}\text{I}-T_3$ ($2 \times 10^{-9}\text{ M}$) was added. The larvae were washed and homogenized after a further 30 min of incubation.

Table 4. DISTRIBUTION OF $^{125}\text{I}-T_3$ IN PROTEIN-BOUND AND PARTICULATE FRACTIONS OF *XENOPUS* HOMOGENATES AT 5°C AND 25°C

Fraction	Developmental stage (days)	Relative distribution		Fraction protein-bound (per cent)	
		5°C	25°C	5°C	25°C
Whole homogenate	1.5	100	100	47	56
105,000g pellet		23	31	53	64
105,000g supernatant		69	73	18	29
Whole homogenate	4.5	100	100	58	73
105,000g pellet		42	72	66	89
105,000g supernatant		54	24	32	59

Larvae obtained at 1.5 days and 4.5 days after fertilization were incubated with radioactive T_3 at 5°C and 25°C , in conditions described in Table 3. A part of the homogenate was separated into the particulate and supernatant fractions by centrifugation at 105,000g for 2 h and the protein-bound radioactivity determined by precipitation with 5 per cent trichloroacetic acid.

chemical or physiological responses and hormone-binding was less close. The latter function seemed to be acquired in two major bursts, one rapidly at 2–3 days after fertilization of the eggs and the other gradually at 6–10 days. The total protein content of the larvae increased very rapidly during the second period.

The reason for the two-step increase in affinity for the hormone may partly lie in different anatomical locations of the binding sites. While no systematic attempt was made to localize or fractionate binding sites, as has been done for steroid hormones, we have performed a preliminary autoradiographic analysis which may give a clue to this problem. Much of the hormone localized in the early forms of larvae was found to be in the region of the tail and gut, tissues that regress during metamorphosis. At later stages, and particularly in 6–10 days old larvae, a large amount of hormone was bound to other areas (such as the head) of the larva which would not regress during metamorphosis. In later stages of tadpoles, it is known that urea excretion (a hepatic function) is more sensitive to thyroid hormone than tail regression¹⁰.

A crude fractionation of the whole larval homogenate showed that much of the labelled hormone taken up from the medium was protein-bound (Table 4). A substantial fraction of the bound hormone was recovered in the 105,000g particulate fraction. The fraction of bound hormone recovered with the 105,000g sediment increased with development and it was this component that exhibited temperature-sensitivity and not that found in the supernatant. This finding suggests that at least a large proportion of the binding sites which appear at 2–4 days after fertilization may be localized in cellular structural elements and therefore do not merely reflect the appearance of circulating T_3 -binding protein. Furthermore, the blood of anuran tadpoles has not been shown to contain strong T_3 -binding globulins of the type found in mammals^{8,9}, nor are the circulating T_3 -binding proteins known to exhibit the temperature sensitivity that has been observed in these studies. In adult mammalian tissues also, a large part of endogenous or exogenous thyroid hormone is recovered in the 105,000g sediment, that is, the microsomal fraction^{8,11}. Of course, a more precise autoradiographic and subcellular localization, as has been attempted for steroid hormones¹², has still to be made for these thyroid hormone-binding sites. Even then earlier cell fractionation studies have indicated that a firm binding in itself does not necessarily indicate site of action⁸.

To conclude, our studies have shown that the acquisition of metamorphic competence by developing *Xenopus* larvae is accompanied by the appearance of thyroid hormone "receptors" which can be distinguished by temperature sensitivity from hormone binding components present at earlier developmental stages. These results have a wider physiological relevance, for a major requirement in understanding the action of hormones is the identification of cellular site(s) at which the hormone initially acts to trigger off a sequence of molecular events. It is generally recognized that the number of hormone-binding sites that are directly involved in the biological action of hormones must be very few relative to the total number of sites capable of interacting with the hormone. The outstanding problem is to find ways of distinguishing between these sites.

Although the work described here has to be extended a good deal further along the lines of the work on steroid hormone receptors¹, it nevertheless initiates a developmental approach to defining a physiological role for hormone binding by target cells.

New Self-incompatibility Alleles produced through Inbreeding

by

K. K. PANDEY

Genetics Unit,
Grasslands Division, DSIR,
Palmerston North,
New Zealand

By drawing a parallel with microbial systems it is possible to envisage a scheme of intracistronic recombinations which could give rise to new self-incompatibility alleles.

ONE of the puzzles of higher plant genetics is the mechanism by which new self-incompatibility alleles are generated. These occur abundantly in natural populations, but extensive artificial mutation studies¹⁻⁶, involving several species and hundreds of millions of pollen grains, have produced no single clear-cut case of mutation of one active self-incompatibility allele to another. Mutations have been produced, singly or simultaneously, in the cistrons of the *S* gene complex which control pollen and stylar characteristics, resulting in the breakdown of self-compatibility, but none have been reported in the structural cistron which controls the specificity of *S* alleles. Several hypotheses have been proposed to explain this failure^{1,7-10}.

Occurrences of new specificities have occasionally been reported in experimental segregating progenies of self-incompatible plants in several species, but these could not unequivocally be proved to be new alleles and were assumed to be the results of contamination by stray pollen^{1,4,11-14}. Denward¹⁵, who worked on *Trifolium pratense* (red clover), was the first to suggest that new specificities regularly arose during inbreeding, and that the earlier reports of the occurrence of new alleles in inbred plants were not necessarily due to contamination. Because *T. pratense* is a widely cultivated pasture species in temperate countries, Denward's (from Sweden) could not reliably exclude the possibility of accidental contamination. But de Nettancourt and Ecochard¹⁶ have reported the occurrence of new *S* specificities in the selfed progeny of a clonal population of *Lycopersicum peruvianum*.

I wish to report the generation of unexpected specificities in an inbred plant of *Nicotiana bonariensis*. In a study of *S*-gene polymorphism in *N. bonariensis*¹⁷ a limited number of plants were grown in a greenhouse from seeds derived from four sources. Tests showed that altogether there were only six incompatibility groups, with between them only four different *S* alleles, suggesting that the seed from the four sources had a common origin. Thus the plants grown were probably fairly inbred. In one of the families of second generation plants which was grown from a compatible cross between two of the apparently normal plants, only four plants were obtained, because of the paucity of seed set and poor germination. One of these plants which was male fertile but female sterile was used as a male parent in several crosses with normal plants, originally with a view to studying the genetics of *S*-gene polymorphism and of female sterility. Several plants in the progeny were found to be of unex-

pected *S* genotypic constitution. Detailed descriptions of the parents and results of the progenies will be published later. I shall discuss now the phenomenon of the generation of new *S* alleles through inbreeding.

Involvement of Inbreeding

The unequivocal finding of the generation of unexpected *S* specificities in an inbred plant of *N. bonariensis*, taken in conjunction with the similar finding in *L. peruvianum*, supports Denward's idea that inbreeding is involved in the generation of new self-incompatibility alleles. But it does not necessarily support the view that inbreeding *per se* is responsible for the creation of new *S* alleles. There is considerable genetic and biochemical evidence that the specificity of *S* alleles is the function of the structural cistron of the *S* complex alone¹⁸⁻²⁷. Other major and minor genes, or their combinations, may drastically alter the strength of the expression of the *S* alleles, in certain cases practically obliterating their effectiveness, but there is no convincing evidence that, by themselves, they can produce new functional specificities. Furthermore, it is difficult to envisage how, in a cross-pollinated species, a new specificity produced by a rare polygenic combination would be present in different plants of a progeny and maintain itself from generation to generation.

Hypothesis

What is the role of inbreeding in the generation of new self-incompatibility alleles? One significant possibility is suggested by the work of Catcheside *et al.*²⁸⁻³², who found genes in *Neurospora crassa* which affect the frequency of recombination between allelic differences of a major gene. Four such specific recombination genes (*rec*) controlling intracistronic recombination have been discovered: *rec-1* controls recombination frequency between *his-1* (histidine-1) alleles, *rec-2* between *his-5* alleles, *rec-3* between *am-1* (amination-1) alleles, and *rec-4* between *his-3* alleles. The increase in recombination frequency may vary with different *rec* genes and may be very large, as in the case of *rec-1* where the factor of increase is commonly 15-20 or more.

Three properties of these *rec* genes seem to be significant in the context of the *S*-gene complex. (1) They are highly specific with respect to the major gene with which they are concerned. For example, *rec-1* which controls recombination in the *his-1* locus is insensitive to *his-3*, and similarly *rec-3* which controls recombination in the *am-1*

locus is insensitive to *his-1*. (2) Physically, they are all remote from the gene they control, that is they seem to be randomly located in the genome. (3) Of the allelic forms of these genes it is the dominant (*rec*⁺) alleles which always restrict the recombination frequency and it is the recessives (*rec*) which always ease the restriction and increase the recombination frequency.

These characteristics of the *icc* genes have led to the proposition that they are regulatory genes^{30,33}, analogous to those described in other organisms^{34,35}. Regulation by *rec*⁺ is most simply envisaged as acting directly at the gene level by the agency of a gene product which prevents either the formation of hybrid DNA or the correction of any consequently mispaired bases^{33,36}.

I propose that the principal mechanism of the generation of new self-incompatibility alleles lies in intracistronic recombinations in the structural cistron(s) of the *S*-gene complex, with a minor role of point mutations and deletions. The term "recombination" is used broadly and may include such a likely phenomenon as gene conversion which may or may not involve crossing over^{36,37}. I also propose that recombination in the structural cistron of the *S*-gene complex, like that in the *his-1*, *his-3*, *his-5* and *am-1* loci, is under the control of regulatory genes of the *rec* type found in *N. crassa*. In the case of the *S*-gene, however, I suggest that not one but several such regulatory genes are involved and have a cumulative effect.

In the outbred plants most of these genes will be heterozygous and, depending on the degree of heterozygosity, the expression of the dominant genes will suppress or nearly suppress recombination at the *S* structural cistron. Inbreeding produces homozygosity of these genes resulting in certain plants which have a considerable number of these genes in the homozygous recessive condition. In these plants, therefore, the suppression of recombination at the *S* locus is greatly reduced resulting in high recombination frequency and, consequently, new *S* specificities. Thus inbreeding is instrumental in releasing the structural cistron from the genetic suppression of recombination, whereas outbreeding maintains this suppression.

It is also possible that transcription as well as recombination of the structural cistron (perhaps of all structural cistrons of the operon as a whole) is under the control of these regulatory genes, as has been suggested by the study of *ad-3* locus in *Saccharomyces cerevisiae*^{33,38}. This may explain pseudo-compatibility which often results from inbreeding.

There are certain interesting evolutionary features of

this suggested mechanism of the genetic control of mutation at the *S* locus. It has an obvious selective advantage of increasing the rate of mutation when the range of *S* alleles is very small and results in inbreeding, and of decreasing or suppressing it altogether when the range is great and facilitates outbreeding. It thus has the potential to impart an extensive flexibility to the system. It ascribes a more defined function to at least a part of the polygenic component of the *S*-gene physiology, and indeed to a part of the polygenes in general. Such an evolution of the *S*-gene complex is not only consistent with all known facts regarding the *S* alleles, but is also in line with the operator-regulator model, considered to be one of the chief bases of the organization and control of major loci generally.

Distinction between "Self" and "Not-Self" in Lower Invertebrates

by

JACQUES L. THEODOR

Laboratoire Arago,
University of Paris,
66 Banyuls-sur-mer

This study of an invertebrate tissue recognition system contradicts the notion that allogeneic ectoderm histo-incompatibility developed late in evolution. An "induced autodestruction" experimental system which has been developed could be useful in the elucidation of some obscure cytotoxicity phenomena.

UNTIL quite recently the acceptance by an invertebrate of material from another member of the same species was considered to be almost the rule^{1,2}. But exceptions to that rule are appearing in the literature; from the sponges upwards there are examples of a distinction between "self" and "not-self". Fusion between young sponges belonging to the same species fails³. Tissue incompatibility has been observed in various groups of cnidarians⁴⁻⁶. An allogeneic anamnestic response seems to be outlined in earthworms^{7,8}. Encapsulation of allo-

geneic material occurs in a gastropod mollusc⁹. No explanation of the mechanism(s) involved in these incompatibility phenomena has appeared. Any metazoan invertebrate is assumed to be able to eliminate or render harmless any foreign material entering the body¹⁰; it has also been suggested that, if there is any recognition system in invertebrates, it could only be non-immunological^{1,2,11}.

We have shown that *in vivo*⁶ and *in vitro*¹² tissue recognition takes place in the arborescent coelenterates

known as the Gorgonacea. Segments of branches taken from two individuals belonging to the same species fail to fuse, although experimental autografts succeed without difficulty. The conclusion that gorgonians distinguish self and not-self is confirmed by observations in nature where autografts occur very frequently. Natural allografts fail even in very favourable conditions⁶ (Fig. 1). We agree with Burnet² that "there is no *a priori* reason why two animals of the same species should not accept transplants from one another". Furthermore, neoplastic formations are not known to occur in coelenterates. But we think that in the frequent cases of gorgonians growing one against the other (Fig. 1) the safeguarding of proximo-distal morphogenetic gradients may be of biological significance in allograft failures.

An antibody-like substance has been found in sea anemones¹³, leading Phillips to conclude that the "immune mechanisms involved in these animals were not essentially different from those believed to be important in vertebrates". The appearance in gorgonian allografted hosts of a substance with passive haemagglutinating properties¹⁴ and suggesting an immune response had led us to similar conclusions, but these results have not been confirmed.

Gorgonian tissue is easy to culture¹²; hundreds of explants (0.4 mm²) can be prepared in a day. They are kept in small individual dishes containing 1 ml. of filtered seawater (FSW). Explants (1:1 in volume) to be tested for compatibility are superimposed one on the other. Xenogeneic explants (*Eunicella stricta* (A) and *Lophogorgia sarmentosa* (B)) are mutually damaged within 1-4 days of contact. The destruction is expressed by the collapse and the disintegration of the tissues. This histopathic effect also appears in allogeneic combinations, but usually after a longer delay. No histotoxicity is revealed when combinations of autochthonous tissues are prepared; these explants fuse and reorganize in spherules or in bean-shaped masses, and can survive indefinitely.

We have used a slight modification of this technique. The sizes of one of the explant's surfaces were in a ratio of 8:1, and thicknesses were similar. The larger explant was the killer explant and the smaller was the target. In these conditions (8:1), destruction was confined to the target tissue, the onset of toxic effects was early and the first macroscopic signs of disintegration were recorded in xenogeneic targets 10-12 h after exposure to the killer tissues. Total disintegration of the target occurred in 24-60 h according to the temperature and to the source specimens involved. An attempt to demonstrate some type of *in vitro* accelerated secondary response in gorgonians failed.

Fig. 1. Failure of fusion between homospecific gorgonians. A line separating the allogeneic tissues is clearly visible.

Fig. 2. Expression of the histopathic effect after contact (1-9 h) followed by the separation of killer and target.

An experiment was designed to specify more precisely the minimal time for the triggering of the disintegration, that is, the time during which the explants have to remain in contact to obtain detectable histopathy. The results are expressed according to the visual estimation (macroscopic) of the percentage of disintegrated tissue recorded at the nearest 10 per cent. The same expression has been used in Table 1. Three hundred and twenty xenogeneic explants (8:1, volume of species A and B) were superimposed at time zero, T_0 . At hourly intervals, $T_1, T_2, T_3, \dots, T_9$, forty of these explants were separated and kept apart in filtered seawater. The expression of histotoxicity was estimated 42 h after T_0 (Fig. 2). Results show that a minimal toxicity is manifest after about 1 h and gradually increases until 9 h. Results of a second experiment with samples taken at shorter intervals show that this minimal effect is already discernible after 30 min.

To discern the features of this tissue recognition system we studied the effects of antibiotics and of an amino-acid analogue on the expression of the *in vitro* xenogeneic and allogeneic histotoxicity. We used 60 µg/ml. of actinomycin D (Merck Sharp and Dohme), 100 µg/ml. of puromycin (Sigma) and 200 µg/ml. of *p*-fluorophenylalanine (Sigma) solutions in filtered seawater. Antagonistic explants in contact were maintained in actinomycin for longer than the time required for the expression of toxicity. Both explants remained intact.

The killer and the target were then treated separately: (a) killer explants were pretreated with actinomycin for 7 h, rapidly rinsed in filtered seawater and combined with untreated target explants; (b) target explants were treated in the same way and exposed to untreated killer explants. Controls included: (c) target explants in filtered seawater; (d) killer explants in filtered seawater; (e) target on killer explants in filtered seawater; (f) target on killer explant treated with actinomycin during the whole experiment. The same experimental design was used with puromycin and *p*-fluorophenylalanine. The results are shown in Table 1.

As Table 1b shows, when the target is pretreated the expression of histopathy is inhibited: 2 per cent, 0 per cent, 2 per cent. On the other hand, when the killer explant is pretreated (Table 1a) the histopathy index reaches 50, 63 and 47 per cent after 24 h, indicating severe damage. In another experiment using actinomycin, and by inverting the factors (species A being the target and B the killer), the indices were 20 per cent for the

Two sets of results are given for each of treatments a to f, which are explained in the text.

treated target, 76 per cent for the untreated one, 0 per cent for the treated killer and 1 per cent for the untreated one. Preliminary experiments with allogeneic explants of species *B* treated with actinomycin D showed similar results. Actinomycin D is known to inhibit synthesis of mRNA; puromycin and *p*-fluorophenylalanine interfere with protein synthesis. No information is available about their effect on the Cnidaria, but the wide zoological range of their activity supports the idea that their properties are the same in these invertebrates as elsewhere. The suppression of histopathology, simply by inhibiting action on the target, strongly suggests the existence of a mechanism involving an auto-destruction of the target explant triggered by the killer explant.

This interpretation is supported by results obtained by treating with actinomycin D a target previously in contact with a killer explant for 6 h. Such contact is sufficient (Fig. 2) to trigger more than 80 per cent destruction of the target. If a classical immunological system was involved, no synthesis would be expected to take place in the target, and destruction would be completed. But after treatment, no sign of histopathology appeared. The target was destroyed only if actinomycin was added after the twelfth hour following first contact. Thus the target seems to be the site of the active process. Species *A* and *B* have very small cells; photonic microscopy provided little information about the sequence of events in the destruction phenomenon.

Classical immunological systems are characterized by an induction phase initiated by antigenic material which penetrates an organism. This inductive phase is followed by a phase of synthesis of "responsive material" directed against the antigens and leading eventually to their inactivation. Destruction in gorgonians is apparently governed by a different mechanism, involving the "induced suicide" of the target explant while the killer seems to be passive. This system, although it can be regarded as unlike a conventional immune response, seems to be part of some kind of "pre-immunology". Two independent groups^{7,8,15-17} have interpreted the

accentuated rejection phenomena in earthworms as a type of anamnestic response. Worms are the most primitive group with a closed system of blood vessels, which is probably essential for an anamnestic mechanism to develop.

The "induced suicide" mechanism suggested here might explain the cell destruction observed in puzzling cytotoxic phenomena¹⁸, which in some cases could be mediated by "non-immune" mechanisms¹⁹. Cytotoxicity in these cases was suggested to necessitate cell membrane-bound action or it could be triggered by a diffusible substance²⁰. Whether there is activation in our system through a phase of the latter type is not known with certainty, although the destruction of remote gorgonian target tissues suggests diffusion.

I thank Dr J. Brachet, Dr A. Bussard, and Dr A. Stuart for suggestions and comments. I also thank Francis Belles (Banyuls/mer) for technical assistance.

Correlation of Subpulse Structure in a Sequence of Pulses from Pulsar PSR 1919+21

by

D. C. BACKER

Cornell-Sydney University
Astronomy Center,
Arecibo Observatory,
Arecibo, Puerto Rico

The fluctuation power spectrum of a sequence of momentary pulse energies formed using an integration gate narrower than the pulse width displays features not visible with a wider gate. The analysis indicates that the class two period is a function of phase within the pulse profile. The statistical constitution of the mean pulse is discussed.

PREVIOUS analyses of pulsar radiation have emphasized (a) average properties such as shape, strength and polarization of the pulses by averaging the data with the primary period (P_1) removed, and (b) pulse energy distributions and fluctuation spectra using a sequence of total pulse energies. The former analysis gives no information about how the average is related to the individual pulses and the latter gives no information about phenomena occurring within the pulse profile. This article forgoes these limitations and presents preliminary results of two statistical analyses of a two dimensional data array of pulse intensity versus pulse phase and pulse number for the pulsar PSR 1919+21*.

A Fourier analysis was performed on a sequence of momentary pulse energies, formed by integrating the received radiation intensity over narrow time gates which

were spaced by P_1 and hence corresponded to the same pulse phase for successive pulses. Repeating the analysis for independent phases converted the two dimensional data array to a two dimensional spectral array of fluctuation power versus frequency and pulse phase.

The second analysis converted the data array into an array of frequency of occurrence of a given intensity versus intensity and pulse phase. This is presented as a contour map of frequency of occurrence on an intensity versus pulse phase plane. These results are used to analyse the class two phenomenon which occurs in PSR 1919+21 and to discuss how the average pulse is constituted statistically.

Observations

The observations were made using the 1,000 foot spherical reflector at Arecibo Observatory with a linearly polarized, phase-correcting line feed operating at 319.5

* The standard notation for pulsars introduced by Turtle and Vaughan¹ is used. PSR 1919+21=CP 1919.

MHz. The received power was passed through a 100 kHz crystal filter, detected in a square law detector and smoothed with an RC time constant of 660 μ s. The detected signal was accurately proportional to the received radiation intensity. The output was sampled by an Adage A/D converter controlled by a CDC computer and written on magnetic tape. The sampling was done at 300 μ s intervals across a window of 120 ms centred on the pulse. The trigger pulse used to keep the window synchronized with the apparent pulsar frequency was created using a frequency synthesizer (HP 5100A) locked to the observatory time standard and a frequency counter (HP 245L) with scalar output. This time base was sufficiently accurate to keep the sampling synchronous with P_1 to within one sample in the 11 min block of data analysed.

Data Reduction

The block of 512 consecutive pulses used for this analysis was selected from several independent recordings of data at different radio frequencies on the basis of its having the largest signal-to-noise ratio. In preprocessing the data a baseline was subtracted from each pulse using the noise level in the window off the pulse. The block of 512 pulses was then ready for the transform and occurrence contour analyses.

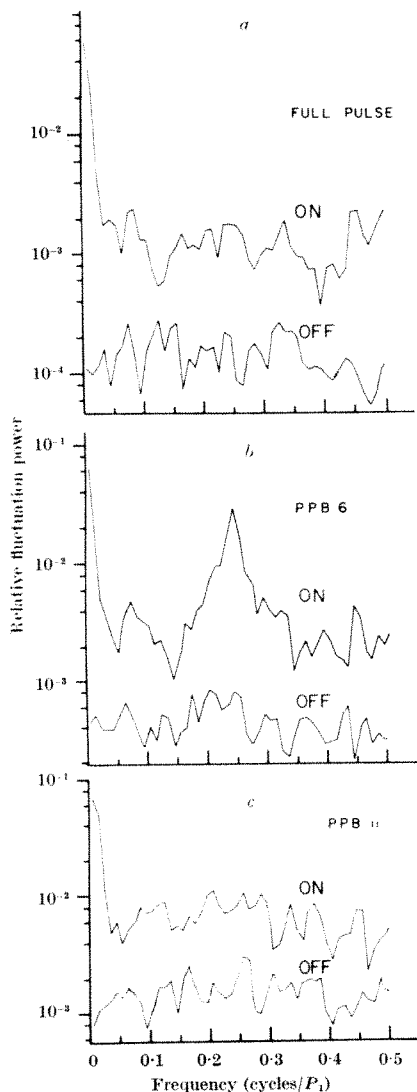

Fig. 1. The pulse energy fluctuation power spectra (ON) in cycles/ P_1 relative to the mean level squared, compared with spectra formed from similar data off the pulse (OFF). The ON spectra correspond to energy in (a) the full pulse (30 ms), (b) pulse phase box 6 and (c) pulse phase box 11.

Fig. 2. Average pulse shape of PSR 1919+21 formed by the block of 512 pulses used in the analysis. Pulse phase box positions are indicated. Date, March 3, 1970. RF frequency, 319.5 MHz; bandwidth, 100 kHz; time constant, 660 μ s; sample interval, 300 μ s.

Two-dimensional Fluctuation Power Spectra

An "on" sequence of 512 numbers representing the overall pulse energies was formed by integrating the intensity over 100 contiguous samples in each window centred on the pulse for each of the pulses. An "off" sequence was formed in a similar manner using data in the window off the pulse. These were Fourier transformed using a Cooley-Tukey algorithm to produce a pulse energy fluctuation power spectrum similar to that presented by Lovelace and Craft². This transform, normalized to the value of the mean "on" level in the sequence squared and smoothed using a running mean over eight frequency components, is shown in Fig. 1a. It differs from that published by Lovelace and Craft by the absence of the feature they found at $\sim 1/(4.39P_1)$. The resolution in the spectrum is 0.016 cycles/ P_1 and the maximum frequency, the Nyquist frequency, is 0.5 cycles/ P_1 .

Twenty-one "on" gated energy sequences were then formed. Each pulse width was broken up into twenty-one pulse phase boxes (PPB) each containing seven samples (2.1 ms). The seven samples in each box were integrated to form a single number. The sequence formed by these numbers for a given PPB was the desired gated energy sequence. For each PPB an independent "off" sequence was formed in a similar manner. PPB 0 coincides with the leading edge of the pulse profile and PPB 20 with the trailing edge as shown in Fig. 2. The same Fourier analysis was performed on each of the twenty-one "on" and "off" sequences. Examples for PPBs 6 and 11 are shown in Figs. 1b and 1c. Each spectrum is normalized to its own mean signal level and is smoothed over eight frequency components. These spectra display four components as has been noted previously^{2,3}. There is (1) a low frequency fluctuation tail; (2) a white, or quasi-white, component; (3) a short period feature; and (4) a long period feature (visible only with less smoothing of the spectra). The measurement of the intense short period feature seen in the spectrum for PPB 6 was the preliminary objective of the analysis. This was a predictable result because the data were known to be very periodic due to the class two phenomenon (see the series of lines drawn to fit the evolution of correlated subpulse structure in a sequence of pulses in the paper by Drake and Craft⁴). The feature was not visible in the pulse energy fluctuation power spectra of Taylor *et al.*⁵ and Lang³. It was visible at a low level in the power spectrum for 6,144 pulses published by Lovelace and Craft² on a logarithmic scale. It is now clear that their response was due to a small residual modulation of the pulse energy which remained even after smoothing over several times P_2 (≈ 15 ms). A spaced overlay of the twenty-one smoothed power spectra in the vicinity of the short period feature is shown in Fig. 3. The scales are linear and vary from one spectrum to the next. The spectra, which were formed from independent sequences of numbers, evolve slowly as a function of PPB. This correlation of independent spectra is related to the typical width of the subpulses which participate in the class two phenomenon. Correlation over three to four PPBs each containing 2.1 ms of data implies a characteristic subpulse width of 7 ms in data with a 2 ms time constant. This interpretation is confirmed in the sequence of pulses published by Drake and Craft⁴ with a 1 ms time constant.

Fig. 3. Spaced overlay of segments of the spectra for 21 pulse phase boxes in the region of the short period feature described in the text. The power scales for the spectra are linear and vary from one spectrum to the next.

Another outstanding characteristic of these spectra is the disappearance of the short period feature in PPBs 9–11. This quantifies the effect also visible in the work of Drake and Craft⁴ that no subpulse peaks are found in the midpulse region (see their Fig. 2a). Finally, there is some evidence of higher harmonics of the short period feature. A secondary peak in the region 0.44 to 0.50 cycles/ P_1 (not shown) and those at 0.27 and 0.22 cycles/ P_1 (visible in Fig. 3) may result from harmonics of the feature at 0.24 cycles/ P_1 when aliasing is taken into account.

A summary of the variation of the centre frequency and strength of this feature as a function of PPB is given in Figs. 4a and 4b. To measure these quantities a baseline in the spectrum was determined on either side of the feature assuming the presence of a white component. The centre frequency was defined as the point at which equal energies occurred on either side in the feature measured above the baseline. The strength was defined as the amplitude ratio formed by dividing the square root of the integrated fluctuation power in the feature into the mean level of the signal for that PPB. Dividing this ratio, which in places exceeds unity, by the width of the feature in frequency components (typically 10–20), gives the fractional modulation of the mean level by the feature. The typical result is roughly 10 per cent.

An important reason for this analysis was to see if the phase variation of the predicted short feature could be used to quantify the class two phenomenon as an average property. In terms of the series of lines that are drawn to match the evolution of subpulses through a short sequence of pulse profiles, the centre frequency of this feature measures the average “vertical” spacing (P_3) of the lines and the gradient of the phase of the power components in the feature across the PPBs measures the “horizontal” spacing (P_2). The Cooley–Tukey algorithm receives a complex input array and produces a complex

spectrum with spectral components S_k derived from the summation in equation (1).

$$S_k = \sum_{j=1}^{512} N_j W^{-jk} \quad (1)$$

where $\text{Re}(N_j)$ = j th data point

$$\text{Im}(N_j) = 0$$

and $W = \exp(2\pi i/512)$, the principal 512th root of 1.

The phase for a given S_k is the angle ϕ_k of the phasor representing S_k on a complex plane.

$$\phi_k = \arctan [\text{Re}(S_k)/\text{Im}(S_k)] \quad (2)$$

If the data contain a periodic component with a phase angle at the origin of ψ , $\cos(2\pi f(k \cdot P_1) + \psi)$, then that frequency component in the spectrum will have a phase $\phi_{k*} = \psi$.

$$\text{Re}(S_k) = \sum_{k=1}^{512} \cos(2\pi f(k \cdot P_1) + \psi) \cos(2\pi \left(\frac{k}{512 \cdot P_1}\right) (j \cdot P_1)) \quad (3)$$

$$\text{Im}(S_k) = \sum_{k=1}^{512} \cos(2\pi f(k \cdot P_1) + \psi) \sin(2\pi \left(\frac{k}{512 \cdot P_1}\right) (j \cdot P_1))$$

For $k^*/512 \cdot P_1 = f$, the summations in equation (3) can be reduced.

$$\text{Re}(S_{k*}) = \frac{1}{2} \cos \psi$$

$$\text{Im}(S_{k*}) = \frac{1}{2} \sin \psi$$

Fig. 4. Summary of the variations observed in the short period feature over the 21 pulse phase boxes. a, The centre frequency in cycles/ P_1 . The broken line corresponds to the region where the feature is undetectable. b, The amplitude ratio of the integrated strength of the features in each PPB spectrum expressed as a ratio of the mean level for that PPB. c, The phase of the frequency component $f=0.240$ cycles/ P_1 as defined in the text. d, The modulation index expressing the ratio of the fluctuation power to the mean level for each pulse phase box.

and therefore

$$\varphi_{k*} = \psi$$

As the correlated subpulses drift from the trailing edge of the pulse width to the leading edge over several pulses, the phase should increase with PPB. Such behaviour does indeed occur as shown in Fig. 4c, the phase against PPB for $f=0.240$ cycles/ P_1 , or $k*=123$. Adjacent frequency components have phase functions of identical shape with a constant offset. A phase increase of 360° indicates that one whole period of P_2 has been crossed in the PPBs and that the phase of the frequency components in the feature for succeeding PPBs is now referred to a new line of subpulses. The slope of the phase function is then a measure of the average subpulse spacing in the class two system of subpulses (P_2). A series of slopes are shown in the corner of Fig. 4c. The spacing is seen to vary slowly across the profile. It is 17.6 ms on the trailing edge where the subpulses first "appear", decreases to 10.7 ms in the midpulse region and then increases to 23.1 ms on the leading edge. This phase function and others suggest strongly that the subpulse spacing increases indefinitely as the subpulses "disappear" from the leading edge. Thus the "march" of the subpulses becomes infinitely fast as the subpulse leaves the leading edge. This inconstancy of P_2 is noticeable in the original data presented by Drake and Craft⁴ (see their Fig. 2a) and may be the cause for inconsistent measurements of P_2 (private communications from Drake and from Vitkevich), because the series of lines to fit the subpulse evolution are usually drawn as straight lines to facilitate analysis of the phenomenon. This result suggests that the "lines" of subpulses are actually S-shaped curves with a constant spacing due to the constancy of the centre frequency with PPB, but with a variable slope related to the variation in the gradient of the phase function over the pulse profile.

Modulation indices (m) for each PPB were computed from the twenty-one spectra and are plotted against PPB in Fig. 4d. Each is computed by finding the ratio of square root of the integrated fluctuation power in the entire spectrum to the mean "on" level. This curve will be discussed later.

Two-dimensional Frequency of Occurrence Map

A smoothed contour map of the frequency of occurrence of a given intensity (ordinate) for a given sample in the window (abscissa) in the block of 512 pulses is shown in Fig. 5. The intensity intervals correspond to two logical levels in the A/D converter and samples are spaced by 300 μ s. Typically 5 to 10 per cent of the samples on the pulse fall below the lower 10 contour while 10 to 20 per cent rise above the upper 10 contour. Cuts through the contours at various sample numbers were compared. The peaks of the resultant histograms follow the mean level closely. The other feature of these histograms is the high intensity side of the distribution. The small block of data prevented a highly significant analysis, but the histograms suggest an exponential tail with a slope dependent on the mean level, the slope being flattest where the pulse is strongest.

Fig. 5. A smoothed map of frequency of occurrence of a given radiation intensity for a given sample number.

Discussion

It is now possible to discuss how the average pulse is related to the individual pulses during a strong burst. The occurrence contour map indicates that the individual pulses are dominated by a constant component. The two-dimensional Fourier analysis indicates the presence of a second component, which is the system of subpulses participating in the class two phenomenon.

From Fig. 4b it seems that the subpulses are modulated by an independent envelope synchronized with P_1 . This envelope has two peaks separated by a null. One peak occurs on the leading edge of the average profile before the first peak; the other is centred in the trailing half of the pulse. The latter peak appears slightly double. This doubling can be explained perhaps by a broadening of the feature in the spectrum into the spectral region used to determine the baseline. Because the null corresponds to a region where P_2 decreases to 10.7 ms (see Fig. 4c), it is possible that the modulation disappears because of a merging of successive subpulses in that region of the pulse. On the basis of these two interpretations of the analysis it is possible to say that the subpulses are modulated by an envelope similar but not identical to that of the long term average pulse shape.

The modulation index variation shows an increase by a factor of two on the leading and trailing edges of the pulses where the mean pulse level is low. The subpulse contributions to that level must be large and infrequent. They are probably the result of an occasional subpulse marching beyond the normal confines of the pulse profile.

The contour map (Fig. 5), because it resembles the mean pulse shape, shows that the variations in the mean pulse across its width are caused by variations of the same shape in individual pulses rather than a variation in frequency of occurrence across the width of more uniform intensities. This suggests that a single phenomenon external to the radiation producing structure modulates the entire pulse. The interpretation that the subpulses are related to the radiation producing structure, and accelerate as they approach the leading edge of the pulse is consistent with this interpretation. The possible variation across the pulse profile of the exponential tail out to high intensities would indicate one property of the external modulating phenomenon.

Finally, there is a long period modulation (P_4) of the pulse energy. It appears in the spectra done for this analysis as two peaks at frequencies near 0.0088 and 0.017 cycles/ P_1 . This feature was first reported by Lang³ and has been discussed by Staelin *et al.*⁶ and Lang (unpublished). It is equally strong in both the non-gated and gated spectra. In particular, it is present in the PPB 10 spectrum where the short period feature vanishes, although that may be due to other reasons. Thus from this analysis, it is not clear whether the long period modulation is related to the correlated subpulse phenomenon⁶ or not (Lang, unpublished). If, in fact, P_2 is not a unique quantity, then there are obvious difficulties in trying to tie the periods P_1 , P_2 , P_3 and P_4 together as Staelin *et al.* have attempted to do.

I thank John Comella, John Rankin, F. D. Drake and the staff of the observatory for help. The Arecibo Observatory is operated by Cornell University under contract with the US National Science Foundation and with partial support from the Advanced Research Projects Agency. This work was partially supported by the US Air Force Office of Scientific Research.

MIRVs and the Strategic Balance

MATHEMATICAL models are a useful aid in describing the strategic balance of deterrence, but must be used with caution. Bellamy¹ uses a model to show that, in certain circumstances, the fitting of multiple independently targetable re-entry vehicles (MIRVs) instead of single warheads on intercontinental ballistic missiles may make the strategic balance more stable. He calculates the number of warheads X_b belonging to side B which would survive a first strike by side A and could then be used against A's cities in a retaliatory second strike. N_b is the number of launchers possessed by B, each with reliability R_b , and with n_b warheads. A fraction f of A's N_a missiles are used for a first strike, and each of the n_a warheads has a probability C_a of destroying one of B's launchers. By assuming a situation in which A and B have identical parameters he obtains a simple expression

$$X_b = X_a = RnN(1 - C)^{fnr}$$

which can be maximized with respect to n . For plausible values of the parameters, the value of n corresponding to maximum X is greater than 1.

A practical question might be asked concerning the assumption that n MIRVs on one rocket are as effective as n single warhead missiles for the purpose of retaliation against cities. An alternative simple assumption is that the n MIRVs on one rocket are only as effective as one single warhead missile against cities, which has some justification on the grounds that the total megatonnage of explosive in the n MIRVs will almost certainly be less than that in the single warhead, and that it may not be possible to aim the MIRVs from one launcher at several widely dispersed cities.

The assumption that $N_a = N_b$ and that the other parameters are identical for A and B is too restrictive for a thorough examination of the stability of the strategic balance. G. D. K.^{2,3} has developed a model which allows A and B to choose different parameters, and a similar model has been used by Saaty⁴ to discuss the effects of multiple warheads.

Our model uses a graphical display to illustrate the state of the balance and hence does not have to assume symmetry to obtain a result. It introduces a "minimum deterrent" U_a , representing the minimum number of missiles which A would have to deliver to B's cities in order to deter B, and a corresponding U_b . Also, to allow for untargetable weapons like missile-firing submarines, a parameter k_b represents the proportion of B's missiles which can be engaged by A's missiles. Taking Bellamy's f and R to be 1, and using his notation, the equations showing the number of A's missiles (N_a) needed to reduce B's second strike strength below the deterrence threshold and still retain U_a to threaten B's cities are

$$\begin{aligned} (N_a - U_a)n_a &= SN_b k_b \\ N_b k_b (1 - C_a)^* + N_b (1 - k_b) &= U_b \end{aligned}$$

and there are similar equations describing B's ability to make a disarming first strike against A.

These curves divide up the domain of positive N_a , N_b , and produce a balance diagram which takes one of the forms shown in Fig. 1. In these diagrams, I indicates the area of mutual deterrence, II that in which A dominates and III that in which B dominates. IV, if it exists, represents a "pre-emptive area" in which the first attacker wins and V a subcritical area in which neither side has enough missiles to destroy the other. In area I, the stability of deterrence for any particular combination of A's and B's stocks, represented by a point P , is indicated by the distance of P from the boundary lines, for this shows how far stock levels can be changed without upsetting the balance.

The application of this model to the case considered by Bellamy is shown in Fig. 2. The parameter values used are $U_a = U_b = 50$, $C_a = C_b = 0.5$, $k_a = k_b = 1$. Curves defining the area of mutual deterrence for values of $n = n_a = n_b$ from 1 to 4 are shown. To avoid confusion the pre-emptive areas which exist when $n > 2$ are omitted. It can be seen that, as n increases, the area of mutual deterrence, and stability, decreases. If the original stocks were 700 each, as indicated by the point P , the situation is very stable when $n=1$ and remains reasonably stable up to $n=3$. When $n=4$, stability has almost disappeared, and when $n=5$, the situation is pre-emptive.

The situation when ABM defence is introduced is illustrated in Fig. 3. This starts with the same parameters as before but fixes $n=3$; the curve labelled "no defence" is therefore the same as that labelled $n=3$ in Fig. 2. To counter the use of MIRVs it is assumed that an ABM defence capable of destroying one out of two incoming warheads is deployed. If this defence is applied to protect cities only, the area of mutual deterrence is

Fig. 1. Types of strategic balance diagram.

Fig. 2. Loss of stability as n increases.

greatly reduced; the point P , representing equal stocks of 700 missiles each, is now near the boundary. On the other hand, when the defence is used to protect missile launchers only, stability is greatly increased, almost to the level where no MIRVs and no defence are used; the case shown by the dashed lines. The asymmetric case where one side has the MIRVs but no ABM defence and the other ABM defence of launchers but no MIRVs is represented by taking one of the "defend launchers" lines with the opposite dashed line, indicating that such a situation departs only slightly from a symmetrical balance.

If we accept Bellany's assumption that the deterrent effect is proportional to the number of warheads rather than the number fired in retaliation, the balance diagram of Fig. 4 is obtained for the case with ABM defence. This demonstrates Bellany's point that MIRV can increase stability, because for values in the vicinity of $N_a, N_b = 40$ (point Q) there can be stability for $n=5$ but not for $n=1$ or $n=10$. For most of the domain of N_a, N_b , however, increasing n decreases stability.

These diagrams also illustrate the difficulties to be faced in an arms reduction programme, if a stable state

with large N_a, N_b , is to be kept stable while reducing the number of weapons.

Modification of Stratospheric Properties by Trace Constituent Changes

It has been suggested that large quantities of water vapour and other pollutants introduced into the stratosphere by supersonic transporters may change the basic properties of the stratosphere¹. But what happens when large changes in trace constituent concentrations occur naturally, for example, after a volcanic eruption? The stratospheric temperature seems to increase by about 5° C and it remains higher than normal for several years. Some of the evidence for this is given in Figs. 1 and 2, which are based on daily upper air data from Australia and New Zealand. Monthly temperature means were formed for each month, then mean monthly values computed from data for the period 1958–62 inclusive. Deviations from these long term values were noted, and a three-month running average obtained. Fig. 1 gives the time variations of these deviations at selected stations. A major eruption of Mt Agung, Bali (8° S, 115° E), occurred on March 17, 1963, and there have been reports of other eruptions that year. Temperature at the low latitude stations increased almost immediately and remained higher than normal for over two years. Fig. 2 contains meridional cross-sections of the temperature deviations

Fig. 3. Effect of MIRVs and ABM defence (deterrence dependent on number of missiles).

Fig. 4. Deterrence dependent on number of warheads (ABM defence present).

Fig. 1. Temperature deviations from monthly averages based on the period 1958–1962. Units: degree centigrade. Pressure level shown in millibars (mb). Australian stations 027: Lae (6.5° S, 147° E), 120: Darwin (12° S, 131° E), 312: Port Hedland (20° S, 119° E), 461: Giles (25° S, 128° E), 865: Laverton (38° S, 145° E). New Zealand Station 780: Christchurch (43° S, 173° E).

for particular months based on station data for the longitude region 110° E to 180° E. At the beginning of 1963, temperature was below the five year normal and the time variations had been following the characteristic southern hemisphere biennial pattern². The eruption interrupted this pattern. The cross-sections bear some resemblance to those for the products of nuclear weapons tests (for example, see the isolines of tungsten 185 radioactivity in ref. 3), as might be expected. The deviation pattern exhibits a maximum at low latitudes in the lower stratosphere and slopes downwards towards the pole, in some cases at a slope greater than that of the potential temperature surfaces. It is difficult to detect the changes, if any, below 300 mbar. While negative values predominate in the examples shown, it was not possible to draw in a -2° C contour. Similarly, at higher latitudes in the stratosphere the effect is uncertain; large deviations from average are more common there. It has been reported² that the Australian Weather Bureau changed its thermistor mounting at the end of 1962. Maps of temperature for January 1963 and 1964 show that the temperature change is present at other longitudes.

not discussed here. The height of those constant pressure surfaces above the dust layer was raised by up to 200 m in January 1964 at 50 mbar. With no obvious compensatory cooling at higher levels, although doubtless the circulation patterns there will adjust somewhat, one might expect to see larger densities measured by the satellite drag technique. I leave a search for this effect to others more conversant with the problems of satellite data.

Measurements of solar radiation at the surface¹² and scattered light from twilight¹³ have been used to trace the cloud from Bali. Temperature deviations may also be used where the data are adequate and we are working on this problem now, using also stratospheric mean wind charts for the period. To assist in this work we would greatly appreciate copies of any reports or reprints dealing with twilight glows, temperature anomalies or surface radiation anomalies. Many people noted the Krakatoa events (see Symons⁶) and the interest in theories of climatic change involving volcanoes was thereby heightened^{14,15}. Bali produced temperature changes in the stratosphere much larger than those normally considered in climatic change discussions.

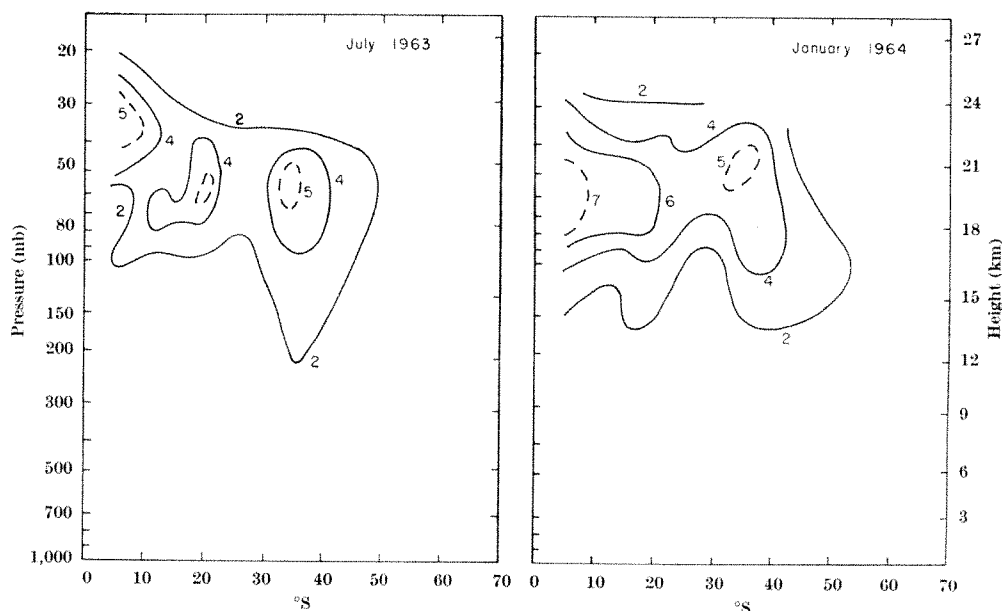

Fig. 2. Meridional cross-section drawn from data for stations used in Fig. 1 and additional stations. Isolines are temperature deviations, during month shown from monthly average based on 1958-1962. Units: degrees centigrade.

If temperature changes of up to 5° - 6° C above average are produced within about 2 months, as seen from Fig. 1, the equivalent heating rate is at least 0.1° C/day, which is a relatively large contribution in the lower stratosphere. The heating is probably caused by absorption of solar radiation by aerosols such as that demonstrated by Robinson⁴ for the troposphere. The exact nature of the particles is unknown, although Mossop⁵, who sampled them directly from an aircraft, comments that the dust seems to be coated with sulphuric acid. Volcanic gases contain large quantities of water vapour, carbon dioxide and sulphur dioxide, and fairly rapid formation of sulphuric acid has been suggested for the Krakatoa eruption⁶. A strong smell of sulphur was reported at Bali⁷. Several workers have suggested that the particles grow *in situ* from the gases introduced into the stratosphere^{5,6,8-11}.

Station data from the northern hemisphere tropics also show evidence of a similar temperature increase. An overall increase of 5° C in the layer 17-25 km over more than one quarter of the globe will evidently produce other geophysical changes. There are obvious items, such as changes in the mean wind field, the evidence for which is

Our work on planetary transport processes is supported by the US Atomic Energy Commission. I thank Robert Crosby for his help and suggestions with the data processing. The Meteorological Services of Australia and New Zealand kindly provided the data.

Evolution of Rifting in Africa

THE recent report by Girdler *et al.*¹ on the rift system of East Africa is of great interest because it presents a crustal model, based on new gravity observations, which suggests an intrusion of low velocity mantle material rising to the base of the sialic crust which underlies the eastern and western rift valleys of East Africa between 3° N and 9° S over an east-west width of about 1,000 km. The crustal model proposed is thus in a general way comparable with the postulated to underlie the worldwide mid-ocean ridge² and the Upper Rhinegraben³. Studies of seismicity, age of faulting, age of volcanoes and short and long wavelength gravity anomalies are interpreted by the authors as indicating attenuation of the African crustal plate and the early stages of its breakup. The structural behaviour of East Africa is compared with the conveyor belt mechanism of sea floor spreading from mid-ocean ridges as recently reviewed by Vine⁴ and rates of movement away from the rift axis of 0.5–2.0 cm yr⁻¹ are said to be indicated.

Such high rates of spreading are hard to reconcile with the geological picture of East Africa which is now known in some detail through the many map sheets published by the Geological Surveys of Kenya, Uganda and Tanzania. The terrain is very different from that of the mid-ocean ridges, as judged, for example, from geological mapping in Iceland⁵. Kenya and Tanzania form part of an extensive Pre-Cambrian platform and Caenozoic volcanism is largely limited to a belt parallel to the Gregory Rift Valley which does not (except for two small volcanic centres) extend south of 3° 30' S. In the Western Rift Valley, the volcanism is limited to two elbows in fault direction and to the junction with the eastern rift at 9° S. Moreover, the volcanic rocks of East Africa are characteristically of alkaline type, whereas those of the mid-ocean ridges are almost entirely of the strongly contrasting tholeiitic type.

The floor of the rift valley itself is much cut by longitudinal faulting, but basement outcropping near the rift margins is not markedly cut by meridional dykes, as would be expected under an east-west tensional stress pattern. Girdler *et al.*¹ do not give the names of the volcanoes used in the computation, nor do they cite any isotope age data in addition to the stratigraphical ages given in the reports of the Geological Survey of Kenya. Many of the volcanoes have been active over quite long periods and, although it is known that the large majority of recent volcanoes and young fault scarps are associated with the relatively narrow rift valley zone, the volcanism had already started here in the late Miocene. On the other hand, activity on Mt Kenya and Kilimanjaro, some distance from the rift, continued into the Pleistocene⁶. Late Pleistocene craters are recorded⁷ in the Nyambeni Range north-east of Mt Kenya, and the craters of the Chyulu Range, north of Kilimanjaro, are presumed to be recent⁸. Both these ranges are over 100 km eastwards from the rift margin. It is therefore difficult to see how a general rule that volcanoes are older the farther they are from the rift axis can be established.

Whether the age of faults can be used as a measure of the rate of distension is also doubtful for the following reasons. The exact age of the rift faults in the area included in the computation of spreading rate is difficult to determine, although it is certainly well known that the youngest scarps are associated with the presently active rift valleys. The Gregory Rift Valley, however, fades out into block faulting to the south of 3° S and this factor must

complicate the assessment of data for even the most approximate calculation of a spreading rate because there is no central axis. Moreover, it is generally accepted that faults originating at least as far back as the Cretaceous have been reactivated at later dates up to recent. This characteristic of some of the faults of the East African rift system in Tanzania is therefore in sharp contrast to the situation on the mid-ocean ridges where the faulting at the axis affects only recent volcanic rocks. The geophysical information published by Girdler *et al.*¹ is of great value, and will help to explain, for example, the typical uparching of the rift belts which has been regarded as responsible for the rifting⁹; but before quantitative estimates of a spreading rate are accepted, much more must be known about the compatibility of the spreading hypothesis with continental crust geology of East Africa.

It has recently been suggested¹⁰ that certain dislocation zones, with local development of rift valleys^{11,12}, in the Guiana and West African shields lined up directly with the pre-drift fractures¹³. It is now widely accepted that these fractures later developed by ocean floor spreading into the basins of the present North Atlantic, South Atlantic and the connecting equatorial segment, which suggests that similar mantle structures underlie both continental and oceanic segments of these lineaments. It therefore seems that there is a similar type of lineament in both continental and oceanic lithosphere which, in the continental environment, may be affected by arching and consequent limited distension, or, in an oceanic environment, may be a locus of the rise of mantle material accompanied by ocean-floor spreading. Similar considerations apply to the Upper Rhinegraben lineament³ and have been suggested for the East African rift system¹⁴.

The East African rift lineament meets the spreading mid-ocean rifts of the Red Sea and Gulf of Aden in the Afar triangle, and it is tempting to seek evidence that the African rift is also spreading, particularly in view of the great volcanic outpourings in Ethiopia, although these are dominantly alkaline and not tholeiitic. But the rift valley and the belt of Caenozoic volcanics are on a scale which can be portrayed in detailed geological map sheets, so that verification of spreading, by reference to criteria now accumulated from the ocean floor rifts, should be possible by means of geological relationships¹⁵. The object of this communication is to indicate that the evidence for spreading at the rates postulated for the Kenya and Tanzania sectors by Girdler *et al.*¹ requires re-examination from the geological point of view because the phenomenon is fundamentally a geological one.

I thank J. V. Hepworth and J. B. Kennerley for valuable discussions.

Pleistocene Sea Levels possibly indicated by Buried Black Sediments in the Black Sea

MODERN surface sediments containing H_2S are often coloured black by fine grained, iron monosulphide minerals such as mackinawite, $Fe_{1+x}S$, and greigite, Fe_3S_4 . The black monosulphides are thermodynamically unstable, under H_2S -rich sedimentary conditions, relative to the disulphide pyrite, FeS_2 ^{1,2}, which is not a black pigments agent. As a result, the black colour normally disappears with depth during diagenetic transformation to pyrite^{2,3}. In some situations, however, such as in older buried layers of the deep water sediments of the Black Sea, the black monosulphides persist.

Volkov⁴ has shown that the black sediment of the Black Sea, when compared with the more common lighter grey sediment, is characterized by low concentrations of pyrite, lower total reduced sulphur, high concentrations of iron monosulphides, and very low dissolved H_2S in associated pore waters. He has suggested that this black sediment results from limited bacterial sulphate reduction during early diagenesis with insufficient hydrogen sulphide formed to enable complete transformation of black "FeS" to FeS_2 . Recent analyses confirm these conclusions (see Table 1). Methods of determination of each constituent have been described previously². Note that the total "reactive" iron content (pyrite iron plus HCl-(soluble iron) does not consistently differ between grey, pyritic sediment and black sediment. Thus the decrease in total reduced sulphur in the black layers must have been caused by a lower original production of H_2S by bacteria.

Limited H_2S production in anaerobic sediments and bottom waters is related primarily to (1) a low concentration of bacterially metabolizable organic matter, or (2) a low concentration of dissolved sulphate. Because the black layers of the Black Sea sediment are not distinctly different in organic carbon content from interbedded grey layers (see Table 1), barring such speculative factors as trace metal bacterial poisoning, the lowered H_2S production during deposition of the black layers must have been caused by a low concentration of dissolved sulphate in the overlying water. In a low sulphate situation, diffusion of sulphate into sediments may be too slow to provide enough sulphur for the complete diagenetic transformation of iron monosulphides to pyrite.

Table 1. MEASURED PARAMETERS FOR A CORE (1464-K) OF BLACK SEA SEDIMENT

Sampling depth range	Colour	Per cent sulphur as—		"Reactive" iron (per cent)	Organic carbon (per cent)
		$FeS + FeS_4$	FeS_2		
152-155 cm	Black	0.58	0.30	6.13	0.56
157-159	Black	0.74	0.22	7.10	0.58
162-164	Black	0.75	0.31	6.47	0.60
166-168	Grey	0.01	1.99	6.42	0.59
172-175	Grey	0.01	1.59	6.27	0.77
181-185	Grey	0.01	1.40	5.19	0.77
239-241	Grey	0.01	1.82	6.31	0.52
247-249	Black	0.33	0.30	5.18	0.59
259-262	Black	0.44	0.20	5.89	0.49
270-272	Black	0.58	0.44	5.76	0.71
279-281	Grey	0.01	2.52	7.06	0.59
284-287	Black	0.45	0.16	5.95	0.60
297-299	Grey	0.01	1.68	6.11	0.58
305-307	Black	0.67	0.30	6.46	0.68
329-331	Black	0.46	0.26	6.35	0.63
341-343	Grey	0.02	1.75	6.34	0.62
347-349	Black	0.39	0.46	6.75	0.73
362-364	Grey	0.02	1.56	5.60	0.87

The core was taken at 43°0' N, 35°5' E, water depth 2,179 m. Percentages are based on $CaCO_3$ -free acid soluble iron-free, dry weight. "Reactive" iron refers to the sum of pyrite iron and that soluble during boiling for 1 min in 12 N HCl.

Present day Black Sea water, which contains about 18 mmoles/l. dissolved sulphate, represents a mixture of fresh water derived from inflowing rivers with a high proportion of seawater derived from the Sea of Marmara by way of the Bosphorus. The sulphate is derived almost entirely from seawater, which contains about 28 mmoles/l. as compared with the rivers, which contain, on average, only 0.35 mmoles/l.⁶. Because of the high contribution

of seawater sulphate, black FeS minerals in the present deep water sediments are completely converted to pyrite⁵, resulting in grey sediment which is similar to the buried grey layers described in Table 1. During the Pleistocene, when the worldwide sea level was sufficiently lowered below the Bosphorus so that seawater inflow was excluded from the Black Sea, the constant influx of river water could have flushed out pre-existing sea salts, eventually resulting in a brackish or fresh bottom water low in dissolved sulphate. During these periods of maximum sea level lowering the black layers may have been deposited. Whenever the sea level rose high enough for seawater to spill over the Bosphorus sill, an influx of sulphate to the deep water would occur and black iron sulphides formed at the same time could be completely converted to pyrite resulting in grey sediment. Thus it is possible that sediment sections containing many black layers record periods of glacial maxima. (The simultaneous change in sea level and appearance of each black layer would not be expected because of complications arising from the interaction of seawater and freshwater in the Bosphorus and from time lags from rates of mixing of the two water types within the Black Sea itself.)

This suggestion must await detailed comparison of the age, thickness and frequency of black layers in undisturbed sections of deep Black Sea sediments with other indicators of Pleistocene sea level change. Preliminary examination of cores from the Black Sea deep basin suggests that the black layers are confined to an overall depth range of approximately the same age span as the last major glaciation. In addition, Markov *et al.*⁷ state that during the last major glaciation, the shallow waters of the Black Sea, as inferred from faunal evidence, were very dilute with salinities of less than 5 parts per thousand, which corresponds to less than 4 mmoles/l. dissolved sulphate. At certain times, the deep water was probably similarly dilute which enabled formation of the black layers.

I thank the Woods Hole Oceanographic Institution for providing Black Sea sediment samples and J. Hunt, D. Ross, and R. F. Flint for their assistance and helpful discussions. I received grants from the Alfred P. Sloan Foundation and the National Science Foundation.

Photosensitized Oxidation of Ammonia by Singlet Oxygen in Aqueous Solution and in Seawater

THE various forms of inorganic nitrogen in seawater undergo complex transformations involving a variety of biological, chemical and photochemical processes which are important for protein synthesis and which determine the development of the marine ecosystem¹.

But the process involving nitrification of ammonia to nitrite and nitrate by chemical mechanisms is still not clearly understood.

Swallow² has recently shown that short lived chemical species such as hydrated electrons can play an important part in seawater processes. Singlet oxygen is another

short lived species the importance of which has recently been demonstrated³, and we have examined its effect on aqueous ammonia and how it could be produced in seawater.

Singlet oxygen was produced by dye photosensitization of aerated solutions of eosin, rose bengal, methylene blue or riboflavin. When a solution containing ammonia, 10^{-2} M, and a dye, 10^{-4} M, is irradiated with visible light which is absorbed by the dye in the presence of air, nitrite and nitrates are produced but none appear if the dye or ammonia is absent under the same illumination conditions. (It has been shown that in some conditions N_2 can be oxidized to NO_2^- by singlet oxygen⁸.) The nitrite ions are determined by colorimetry using Bendschneider⁴ and Robinson's method⁴ and the nitrate ions by Taras's method⁵ using phenol disulphuric acid. Experiments were also carried out in seawater to which ammonia and dyes were added. Identical results were obtained.

The nitrite and nitrate yields are small. Exposing the solutions described here, adjusted to pH 8.5, to a 300 W tungsten lamp in a Pyrex cell, gives about 10^{-5} M of both ions after 2 h of illumination. The yields increase with pH, which indicates that the oxidized species is NH_3 rather than NH_4^+ .

Dyes in aqueous solution are destroyed by light even in the absence of added solutes. The decomposition is even more rapid in the presence of buffer mixtures such as phosphates, carbonates and borates, whether in oxygenated or in unoxxygenated solutions. Because oxidation of leuco dyes by oxygen in water gives peroxides⁶, we have checked that this process is not responsible for the oxidation of ammonia.

We also prepared singlet oxygen by another procedure, using an apparatus designed by Douzou and Balny⁷. Hydrogen peroxide and sodium hypochlorite are allowed to react in one compartment, producing singlet oxygen which is carried by a stream of nitrogen to another compartment 3 cm away where it is bubbled through an ammoniacal solution. Nitrite and nitrates are produced, but again in small quantities, and the yields also increase with the pH of the solution. We therefore conclude that singlet oxygen, $^1\Delta$, is able to oxidize ammonia in aqueous solution.

Numerous aromatic compounds in seawater can photosensitize the production of singlet oxygen. Among the substances which absorb in the visible range, riboflavin seems to be the most promising species, although its concentration is very small. With substances which absorb in the near ultraviolet, the photosensitive process competes with direct photo-oxidation of ammonia⁸. We have found that this latter process becomes very important with light of wavelength below 320 nm.

It would be interesting to estimate the amount of nitrification in seawater from the photosensitized mechanism, and to extend this finding to other media, such as waste water containing ammonia and organic compounds.

We thank Professor Creach and Dr Uliana for suggestions and for helpful discussion, and Drs Douzou and Balny for allowing us to use their apparatus.

New High Temperature Carbon Fibre Composite

We have prepared in this laboratory carbon composites reinforced with carbon fibres which have flexural strengths of 120,000 to 140,000 pounds per square inch at room temperature and 125,000 to 150,000 pounds per square inch at 1,500° C (in helium). The composites are reinforced unidirectionally with carbon fibres which make up 75-80 per cent of the total by weight. Densities range from 1.4 to 1.64 g/ml.

The composites are prepared by impregnating Morganite I carbon fibre bundles with one of several possible resins in solution, evaporating off the solvent in vacuum and curing the sample in a mould under heat and pressure. The resulting carbon fibre reinforced polymer composite is then heated in vacuum at high temperature (700°-1,000° C) to carbonize and volatilize the polymer. This treatment is followed by the deposition of pyrolytic carbon within the resulting porous structure using a hydrocarbon gas at high temperature in carefully controlled conditions. By this technique it is possible to replace all or more of the weight lost on pyrolysis with pyrolytic carbon. This can be done in a few hours for small samples made from polymers giving a high char yield, but better results are obtained by extending the deposition of carbon to longer periods.

The flexural strengths were obtained on samples 1.5 inches long, 85 mils wide and 53 mils thick with a span of 1.2 inches and a loading nose with a radius of 3/8 inch moving at 0.05 inch/min. The stress-strain curves were straight and their slope yielded an elastic modulus of 20-30 million pounds per square inch for the composites. All of the failures were caused by crushing on the compression side. Interlaminar shears run on the same sized samples with a span of 0.3 inch and a loading nose radius of 1/16 inch gave values from 2,000-4,500 pounds per square inch at room temperature.

The impact strength of these composites is comparable with the impact strength for epoxy matrix composites made with the same carbon fibre. This high strength, however, must be set against the poor resistance to oxidation of these composites at high temperatures.

Ageing at 500° C in air for eight hours reduced the interlaminar shear strength to less than 50 per cent of the original value. Methods of protecting the composites from oxidation and improving interlaminar shear are now being investigated.

Fuller details of this procedure will be made available after patent applications now pending have been granted.

Polyethylene Spherulites

THERE has been some controversy about the report that polyethylene does not produce spherulites resolvable with a light microscope¹⁻³ but instead produces a complex birefringent mass made up of units less than 1 μ m in diameter (see Figs. 1 and 2 of ref. 1). Previous reports that polyethylene readily produces spherulites, 0.1 to 1.0 mm in diameter^{4,5}, have been attributed to the use of excessive pre-heat treatment above 250° which degrades the polymer, produces excessive thinning of the sample films and destroys nuclei. Organ (private communication), however, considers that the lack of resolution is entirely due to

sample thickness effects such that the large amounts of birefringent material present cloud the contours of the spherulites, which can be clearly observed with samples of 10 μm thick or less.

Thin films of 'Rigidex' polyethylene, 10 μm thick, were observed to exhibit well defined spherulites, 2-5 μm in diameter, and on subsequent melting and re-crystallization the granular birefringent patterns observed before¹⁻³ were reproduced. On melting, the thin films were observed to collapse into very much thicker globules. Similar studies with Marlex-60 samples were inconclusive, for the thin films (4 μm thick) exhibited no well defined spherulites.

In order to define the structural units present in the Marlex-60 the surfaces of bulk and thin film samples were examined with a 'Stereoscan' scanning electron microscope. In each sample, crystallized both in bulk and in thin films, the same structural unit of predeterminedly nucleated spherulites was observed. All the diameters (0.2-1.5 μm) were consistent with those estimated in ref. 1.

Table 1. POLYETHYLENE-MARLEX-60 SAMPLES

Fraction	Weight average Molecular weight	Dispersity Mw/Mn	Texture
A	142,000	7.4	Very coarse
B	41,200	1.6	Fine
C	98,900	3.1	Coarse
D	165,400	2.1	Fine

Two extreme morphologies of the spherulites were observed (see Figs. 1 and 2), (a) of equally sized close-packed spheres with a fine structure of concentric rings and (b) of equally sized spherical bundles of coarse fibres. Despite the complexity of the second morphology, spherical contours can be seen clearly at low magnification and spherulitic growth was obviously present. Other samples of Marlex-60 exhibited this coarse texture to different degrees, which appeared to correlate closely with the dispersity of the samples (see Table 1). This is in agreement with "impurity" segregation theory of spherulite crystallization⁶ in which the less crystallizable materials of lower molecular weight are rejected by the growing face; growth then develops from fibres which grow branch laterally⁷.

The morphologies also correlated closely with those observed in the larger spherulites observed in polyethylene^{4,5,8} and indeed the spacings between the fine structure of concentric rings (0.5-5.0 μm) are consistent. Because there is no difference in morphology, differences between the polyethylene samples lie in their thickness and also in the density of primary nuclei present. Bulk crystallized polyethylene clearly has a spherulitic texture.

Fig. 1. Sample D crystallized at 124.0° C ($\times 4,500$).

Fig. 2. Sample A crystallized at 124.0° C ($\times 4,500$).

It has been suggested that preferential electron etching on the polymer surface of low molecular weight regions, shown in Fig. 2, may have high-lighted the spherulitic structure. This, however, in no way alters our conclusions.

Ionization, Attachment and Breakdown in SF₆

SULPHUR hexafluoride is widely used as an insulator in many electrical devices, but little is known of its fundamental electrical properties, particularly at voltages above about 100 kV. As the first part of an investigation on the growth of pre-breakdown ionization in SF₆, we have carried out measurements from which values of the apparent primary ionization coefficient α' have been determined, at pressures in the range from 50 to 400 torr and for voltages up to about 200 kV. We report here a dependence of the coefficient α' on gas pressure, not previously observed in SF₆, which is significant to the insulating properties of the gas and which can be related to the fundamental collision processes occurring.

At low pressures ($< 10^{-5}$ torr), previous single collision experiments^{1,2} indicated that the main negative ion

species formed in SF_6 by electron collisions were SF_6^- and SF_5^- . In addition, the negative ion currents were observed to depend on pressure rather than on the square of the pressure, which, in the case of SF_6^- , indicated that the ions were in an excited state. Subsequent experiments³⁻⁵ showed that the lifetime to autodetachment of the excited ion $(\text{SF}_6^-)^*$ is very long, $>10^{-6}$ s.

At relatively high pressures (≥ 10 torr), experiments⁶ on the movement of electron swarms in SF_6 have shown that, at these pressures also, both SF_5^- and SF_6^- ions are formed, the relative abundance being dependent on the ratio E/p_{20} (where E is the electric field and p_{20} the pressure reduced to 20° C). At these pressures the $(\text{SF}_6^-)^*$ ions formed in electron collisions with gas molecules make a large number of collisions during their lifetime, so that it is likely that the observed SF_6^- ions are collision stabilized. If this is the case, the attachment coefficient would be expected to be dependent on p_{20}^2 . Measurements^{6,7} of attachment coefficients to date, however, do not seem to indicate such a dependence over the pressure range from 5 to 100 torr. In order to investigate further this apparent contradiction, it seemed worth while to carry out further pre-breakdown ionization measurements over an extended range of gas pressures up to 400 torr.

The apparatus and experimental procedures used were basically the same as those described previously⁸, only slight modifications to the equipment (such as placing activated alumina traps in the pressurizing line and ionization chamber, for example) being necessary for the work with SF_6 .

Measurements were made of the ionization currents as a function of electrode separation at one value of $E/p_{20} = 118 \text{ V cm}^{-1} \text{ torr}^{-1}$. The ionization chamber was filled to a pressure of about 400 torr with SF_6 from a high pressure gas cylinder supplied by Laporte Industries Limited, the quoted impurities being 0.05 per cent of air, 0.05 per cent of CF_4 and 15 p.p.m. of water vapour. Measurements were obtained at this pressure and also for the same sample after reducing the pressure in seven steps, each of 50 torr. A least squares procedure for curve fitting⁹ was used to analyse the measurements in terms of the equation

$$\frac{I}{I_0} = C \left\{ \frac{\alpha' + a}{\alpha'} e^{\alpha'd} - \frac{a}{\alpha'} \right\} \quad (1)$$

where I is the ionization current at an electrode separation d ; $I_0 = I_0/C$, where I_0 is the initial photo-electric current and C is a constant; the coefficient α' is the apparent ionization coefficient given by $\alpha - a$, where α is the Townsend primary ionization coefficient and a the attachment coefficient.

Because I is exponentially dependent on $\alpha'd$, the coefficient which is determined with greatest accuracy in this type of experiment is α' . The errors in the determination of a are much larger, so that any dependence of a

on the square of the pressure is, in fact, most likely to be detected through its effect on α' . The values of α'/p_{20} determined in our investigation are given as a function of pressure in Fig. 1, and it can be seen that α'/p_{20} decreases as the pressure increases, the variation being well outside the experimental error, which is about ± 2 per cent. This variation indicates that in SF_6 , in the conditions of the investigation, one or more processes are operative which depend on the square of the pressure. Bearing in mind the previously determined existence of SF_6^- ions in swarm conditions, it seems likely that this process is collisional stabilization of $(\text{SF}_6^-)^*$ ions, which are produced in the swarm by electron collision.

The work is now being extended to other values of E/p_{20} and to an investigation of whether there are departures from Paschen's law in SF_6 as implied by these results.

Rate Equations in Thermogravimetry

MacCallum and Tanner¹ have argued persuasively for modifying the rate equations used in thermogravimetry, but their conclusions are incorrect. There is no fundamental error of the kind they suggest in the usually accepted procedures and some other reason must be found for discrepancies in derived kinetic parameters. In the present context the point at issue has been dealt with by Kissinger², as follows.

"When the temperature is changing with time, the reaction rate is

$$\frac{dx}{dt} = \left(\frac{\partial x}{\partial t} \right)_T + \left(\frac{\partial x}{\partial T} \right)_t \cdot \frac{dT}{dt}$$

The rate of change of x with temperature, with the time coordinate fixed, $(\partial x / \partial T)_t$ is zero, because fixing the time, also fixes the number and position of the particles constituting the system. The only effect of an instantaneous change in temperature is in the velocity of thermal motion of the particles."

Thus dx/dt always equals $(\partial x / \partial t)_T$, so that the chemical reaction rate is given by the slope of a plot of x against t whether the temperature is varying or not.

It is possible that confusion arises when chemical change is thought of as contributing to the state of a system, rather than as a means whereby states are transformed. The situation is analogous to that of the arrow in flight³, considered by Zeno; although the arrow is in motion, at any instant it is at rest. Similarly the state of a system, reacting chemically can be defined at any instant of time, without reference to change and provided we make an exception of processes so fast that the identity of chemical

Fig. 1. α'/p_{20} , p_{20} at $E/p_{20} = 118 \text{ V cm}^{-1} \text{ torr}^{-1}$.

species and the meaning of temperature are in doubt, this definition can be put in ordinary thermodynamic terms. In thermal analysis change is so slow that temperature has its usual thermodynamic significance, so that $(\partial x/\partial T)_t$ is effectively zero in the experiments considered by MacCallum and Tanner.

Rate of Hydrogen Dissociation at a Hot Tungsten Surface

THE atomization of molecular hydrogen at a hot tungsten surface has been studied extensively, some of the discussion being concerned with the correctness or otherwise of Langmuir's¹ early work. Moore and Unterwald² have summarized the various investigations up to 1964. In particular, it has often been stated that Langmuir's rates were "too low by factors which were all greater than 200", the quoted assertion being first made by Bryce³ but often repeated since then (see for example refs. 3-6).

Langmuir used two techniques to measure the atomization rate. The first relates the rate of heat loss from a tungsten filament in a hydrogen atmosphere to the atomization rate, and is the more reliable². In the second, the rate of removal of hydrogen by an "atom trap" is assumed to be equal to the rate of production of atoms by the hot filament. Until mass spectrometric methods were introduced, only the latter of these two techniques was used by other workers, and it is their results which are said to conflict with Langmuir's work. Recently, Roberts and Young⁷, in studies of the kinetics of the interaction of hydrogen atoms with lead films, concluded that the incorporation of hydrogen into the lead lattice is activated, and is the slow step. At 78 K the rate of incorporation is a factor of nearly 100 slower than that observed with the film at 300 K. This result, like the earlier one of Anderson and Ritchie⁸ with sodium films, implies that atom traps can vary in their trapping efficiency and in general are not expected to be perfect, still less to give rates much in excess⁶ of those derived from heat loss measurements. We have accordingly examined the evidence for the alleged discrepancy (the factor of > 200 by which Langmuir's rates were alleged to be too low) and conclude that it is without justification.

The most careful of the atom trap studies is that of Brennan and Fletcher⁴, who obtained the following expression for the atomization rate n (atoms s⁻¹ (cm² of W)⁻¹)

$$n = 18 \times 10^{24} \sqrt{p} \exp(-52,600/RT)$$

where p is the hydrogen pressure in torr.

Strictly speaking, this result holds only up to 1,400 K, and extrapolation to higher temperatures, necessary for comparison with Langmuir's heat loss data, would not be justified if the hydrogen pressure were less than 10⁻³ torr (ref. 4). Consider first Langmuir's heat loss data (over and above that caused by radiation and convection) for a hydrogen pressure of 1.5 × 10⁻² torr and in the temperature range 1,800-2,900 K (ref. 1, page 435). The atomization rate can be computed from these data by equation 17 of ref. 1, page 427. For example, at 1,800 and 2,100 K, the rate is found to be 8.4 × 10¹⁷ and 5.7 × 10¹⁸ atoms s⁻¹ (cm² of W)⁻¹ respectively, the requisite heats

of dissociation being taken from Stull and Sinke⁵. The corresponding values from Brennan and Fletcher's equation (4) are 9.1 × 10¹⁷ and 7.4 × 10¹⁸ atoms s⁻¹ (cm² of W)⁻¹, which are in good agreement with Langmuir's values. Even Bryce's data, which are considered to be in error from poor vacuum techniques, yield rates at 1,800 K and 2,100 K of 1.0 × 10¹⁸ and 6.4 × 10¹⁸ atoms s⁻¹ (cm² of W)⁻¹, again in close agreement with Langmuir. The comparisons are almost as good if made at a hydrogen pressure of 1.1 torr, for which Langmuir also provides heat loss data.

Langmuir himself did not rate his second technique, in which atoms were trapped on a cooled glass surface, as highly as the first (ref. 1, page 452). Nevertheless, the results obtained from it compare favourably with those obtained by Bryce, who used the much more efficient MoO₃ trap. According to Langmuir's experiment 160 (ref. 1, page 541), the rate of hydrogen uptake on the cooled glass surface of the containing vessel was 1.4 mm³ min⁻¹ (cm² of W)⁻¹ at a hydrogen pressure of 1.5 × 10⁻² torr and a tungsten temperature of 1,200 K. This corresponds to a rate of 1.3 × 10¹⁵ atoms s⁻¹ (cm² of W)⁻¹ and compares favourably with the data of Bryce which yield a rate of 1.9 × 10¹⁵ atoms s⁻¹ (cm² of W)⁻¹.

NMR Relaxation in Heterogeneous Systems

THERE has recently been some discussion^{1,2} of the difficulties of interpreting nuclear magnetic resonance line broadening in complex heterogeneous suspensions. The discussion has been concerned with hindered rotation of solvent species, and it has been confined to proton magnetic relaxation. We report here a study of the relaxation phenomenon in a well defined physicochemical system and contrast the results for proton and deuteron relaxation.

It is well known to NMR spectroscopists that particulate matter in a sample tube causes line broadening. The exchange of solvent species between the bulk phase average local magnetic field and that which exists near suspended matter is sufficient to cause broadening, and no reference to ordering or disordering of solvent is necessary to interpret it. The parameter necessary for interpretation in terms of disordering is the intra-term³ for the spin-lattice relaxation time (T_1) which is obtained, only with great difficulty, from proton relaxation, not to mention line-width (or free induction decay), measurements.

A model system with quite well defined surface to volume ratios may be constructed by packing spheres of known radius in an NMR sample tube with the excess volume filled with water. Glass spheres with quite uniform diameters down to 15 μm are now commercially

available (Microbeads Div., Cataphote Corp.). In addition, they are available with a monomolecular surface coating of a silicone compound (dimethylsilane). Under microscopic examination these spheres, made of optical crown glass, are very smooth and have a narrow distribution of diameters within the manufacturers' specified characteristics.

Fig. 1 shows the results of proton T_1 (null point) and T_2 (Carr-Purcell-Meiboom-Gill) measurements as a function of radius for coated and uncoated spheres at 30 MHz and 26.5° C. The samples were carefully packed to constant and equal total volumes.

Fig. 2 shows similar results for T_1 (adiabatic fast passage⁴) for deuterium in $^2\text{H}_2\text{O}$ in analogously prepared samples.

Two conclusions are immediately clear from these figures. First, T_2 measurements, properly carried out by the spin-echo Carr-Purcell method, are not sufficient for determining rotational reorientation times for protons since $T_2 \ll T_1$ in all the systems. Second, proton measurements in such systems cannot be used to derive an intra-term, and therefore rotational reorientation times, because the change in proton T_1 as the surface-to-volume ratio rises is very much larger than that for deuterium T_1 . Clearly, the proton inter-term has become very important.

The explanation for the above is not difficult to find, and has been discussed quantitatively for protons at much lower surface-to-volume ratios than described here⁵. Essentially, in heterogeneous systems such as this, the effective self-diffusion coefficient of the water molecules is greatly reduced because of mechanical trapping of molecules in surface crevices and between surfaces. Thus, for protons, the inter-term, which is of the same magnitude as the intra-term at low surface-to-volume ratios, becomes very large. The effects observed in proton T_1 measurements in such heterogeneous suspensions are dominated by the inter-term and cannot be interpreted in terms of solvent rotational mobility effects. This conclusion holds true in studies of biological and non-biological systems. It is not true in $^2\text{H}_2\text{O}$ systems where the inter-term is negligible⁶.

Fig. 2 shows that there are changes in rotational mobility at such surfaces, as described here, and that the mobility changes when the nature of the surface changes. The magnitude of the changes is, however, very much smaller than might be inferred from properly interpreted proton relaxation experiments.

Similar remarks apply to all experiments on heterogeneous and colloidal biophysical systems because they depend on large surface-to-volume ratios.

I thank Dr R. C. Hirst of Mobil Research Laboratories for the use of his NMR PS-60 pulsed spectrometer for

Electronic Conduction across a Black Lipid Membrane

BLACK lipid membranes (BLM) have been found to be useful and realistic models for biological membranes¹, showing selective ionic^{2,3} and proton^{4,5} permeabilities, differential negative conductance^{6,7}, the photovoltaic effect⁸, excitability⁹, ability to support active transport¹⁰ and the capacity to interact with leucocytic granules¹¹. Biological membranes may also function in the transport of electrons between redox carriers on opposite sides of the membrane: Mitchell¹² has advocated the coupling of such electron transfer with transmembrane proton translocation as an essential aspect of energy conservation in the redox process of the respiratory chain in mitochondrial and photosynthetic systems. We describe here a partial model for this process in which electronic charge transfer occurs across a BLM.

Two considerations suggest that a combination of iodide and iodine may serve as a mediator for electron transfer across thin membranes. First, these species in combination increase the conductance of certain BLM by several orders of magnitude^{13,14}. This fact evidently reflects the tendency of these species to form triiodide, I_3^- , and polyiodides, I_n^- , which, because of extensive charge delocalization, have substantial affinity for lipid membranes. Second, poly-

Fig. 1. Proton relaxation rates and diameter of glass beads for suspensions of unispheres in H_2O . "Shift" refers to change between uncoated (left side) and coated (right side) beads of the same diameter.

Fig. 1. Zero volt current across BLM as a function of iodine concentration on one side. Iodine solution in M/25 KI, together with suitable buffer and other additives, gave the required iodine concentration. The direction of electron flow was towards the side containing iodine.

iodides have unfilled *d* orbitals at low energy which might be used in electron conductance. Moreover, iodide, iodine and polyiodides take part in several redox reactions, so that these species may participate both as components and mediators in such reactions.

In one case, the I^- - I_2 induced conductivity increase across a BLM has been shown to result from ionic, not electronic, conduction¹³. This observation does not, of course, eliminate the possibility of electronic conductance, particularly when a BLM of abnormally high resistance to ionic conduction is used.

The BLM studied here is constructed from 1 per cent oxidized cholesterol¹⁵, octane-dodecane and didodecyl phosphate as previously described¹⁰, and is supported on a 1 mm diameter hole in a septum of a two-compartment 'Teflon' chamber. Electrical measurements were made as previously described¹⁰. In all the experiments reported here, the membrane was bathed on both sides by aqueous solutions containing 0.10 M NaCl, 0.01 M KCl, 0.01 M MgCl, and 0.02 M *tris*(hydroxymethyl)aminomethane, pH 7.4. All measurements were made at 25°C. This membrane has a resistance of about $\sim 10^{10}$ – $10^{11} \Omega \text{ cm}^{-2}$.

In accordance with previous observations^{13,14}, addition of I_2 ($5 \times 10^{-4} \text{ M}$) and KI (0.025–0.04 M) to the solutions bathing the membrane reduces the resistance dramatically, to $2.6 \times 10^3 \Omega$ in this case. A plot of diffusion potential against the logarithm of the ratio of iodide ion on the two sides of the membrane is linear, with a slope of 60 mV per concentration decade when the ratio is 10 or less¹³. For higher ratios, the plot becomes non-linear with a continuously decreasing slope.

Addition of iodine to the compartment on one side of the BLM under conditions in which 0.04 M KI is present on both sides causes a net flow of positive current across the BLM from the side containing the iodide to the other. As shown in Fig. 1, a plot of the logarithm of net zero volt current flow across the membrane against the logarithm of iodine concentration is nearly linear: the corresponding non-logarithmic plot is sigmoidal with appreciable current observed above $5 \times 10^{-5} \text{ M}$ iodine and saturation approached near $4 \times 10^{-4} \text{ M}$. In these conditions, only 1–3 mV of open circuit voltage developed.

Similarly, addition of thiosulphate ($\sim 1 \times 10^{-4} \text{ M}$) to one side of the membrane when the other compartment contains an excess of iodine elicits a net flow of positive

current across the BLM from the side containing the iodine to the other. This current flow is accompanied by an increase in membrane resistance, perhaps as a consequence of diminution of iodine concentration.

The direction of current flow in these systems establishes that the conductance across the membrane is electronic; ionic conductance would require the current to flow in the opposite direction. Both the sign and magnitude of the diffusion potential require that the conductance be due to anionic species. We must therefore have redox reactions across the membrane, mediated by polyiodide ions spanning it, which may be schematically visualized in the following way:

These two redox reactions occur by way of electron transfer across the BLM without appreciable transfer of any iodine-containing species. This conclusion is based on the following observations: (i) No flux of ^{131}I across the BLM could be detected over 30 min in conditions of diffusion, under the influence of a favourable electrical field, or under the influence of iodine or thiosulphate gradients, even though the resistance of the BLM in the presence of iodine and iodide (2.6 – $3.4 \times 10^3 \Omega$) is only 3–5 times greater than that for the same system without a BLM, $0.8 \times 10^3 \Omega$. In the absence of a BLM, ^{131}I is equilibrated between the two compartments with a half-life of about 3 min. (ii) Moreover, under conditions of passage of $1 \mu\text{A}$ (10^{12} charges/s) across the BLM for 45 min, not more than 0.002 per cent of ^{131}I initially added to one side

Fig. 2. Flux of ^{131}I across BLM in various conditions. Concentration of KI in both compartments was kept at 5 mM in all experiments.

of the membrane is transported to the other, although simple calculations indicate that at least 10 times this amount, even ignoring simple diffusion, ought to have been transported if the conductance were ionic. These results are summarized in Fig. 2. In an effort to understand something about the nature of the process in the BLM which accounts for the electronic conductance, several aspects of BLM behaviour in the presence of iodine-containing species are being investigated; results will be published soon. Overall, these observations are consistent with polyiodide-mediated electron transfer across the BLM.

Qualitatively similar results to those just described have been obtained using a lecithin:cholesterol:tetradecane and a lecithin:tetradecane BLM. The corresponding isotopic flux experiments have not been performed with these membranes.

BIOLOGICAL SCIENCES

Chromosome Breakage by Deoxyribonuclease

THE possibility that endogenous deoxyribonuclease might play a part in inducing chromatid breakage was suggested by our experiments describing a high incidence of chromosome breaks and rearrangements in human diploid cell strains after selective damage to lysosomes¹. We describe here a similar effect when exogenous deoxyribonuclease is introduced into cells in the presence of hypertonic MgSO_4 . This is a modification of the method used by Wecker² in assays of the infectivity of extracted viral nucleic acid.

Pancreatic deoxyribonuclease, recrystallized once, was purchased either from Worthington Biochemicals (approx. 2,400 kU) or from Sigma, electrophoretically purified (approx. 1,900 kU). The enzyme was dissolved in 1.5 M MgSO_4 at a final concentration of 1,200 kU/ml. and stored at -20°C . Thermal inactivation was effected by standing the solution of enzyme in MgSO_4 in a boiling water bath for 20 min. Highly purified lysosomal deoxyribonuclease, extracted from hog spleen³, was dialysed overnight against

1.5 M MgSO_4 before use (final concentration = 330 U/ml.). *Escherichia coli* endonuclease and exonuclease (20 U/ml.) were purified as described⁴ elsewhere. The double-stranded polyribonucleotide, poly A-poly U, which is a competitive inhibitor of lysosomal deoxyribonuclease⁵, was dialysed against 1.5 M MgSO_4 , dispersed by ultrasonic vibration and mixed with lysosomal deoxyribonuclease immediately before addition to the cell sheet. Spectrophotometric studies confirmed that both enzyme and inhibitor were present in the solution. Pancreatic deoxyribonuclease acts by splitting one or another of the two strands of the DNA molecule. The kinetics show "double-hit" cleavage of the duplex. By contrast the lysosomal enzyme attacks double-stranded DNA by splitting both strands simultaneously at the same level. The kinetics show "single-hit" breakage of the double strand. *E. coli* endonuclease preferentially attacks native double-stranded DNA with single-hit kinetics of cleavage of the DNA duplex. *E. coli* exonuclease cleaves mononucleotides from the 3' hydroxyl ends of a single strand of DNA.

In most experiments, the WI 38 strain of diploid human embryonic lung cells⁶ was used. Culture methods were described previously¹. In one experiment adult human diploid fibroblast cultures, grown in the same conditions, were used.

For the hypertonic treatment, nucleases were introduced into the cells approximately 20 h after trypsinization by the following method. Medium was replaced with 5 ml. Mg^{2+} -saline (0.02 M MgSO_4 in Ca^{2+} -free phosphate buffered saline, Dulbecco 'A' medium, pH 7.0); the cells were incubated in this for 15–20 min at 37°C and rinsed with a fresh solution of Mg^{2+} -saline. After being drained thoroughly, the cell sheet was treated with 1 ml. of 1.5 M MgSO_4 (pH 5.5) containing the required concentration of enzyme and rocked for 15 min at room temperature. The cells were rinsed three times in growth medium before being returned to normal culture conditions. In some control groups the culture medium only was changed; others were treated with Mg^{2+} -saline and 1.5 M MgSO_4 , omitting the enzyme.

In some experiments hydrocortisone (Merck) was added to the culture medium at a final concentration of 500 $\mu\text{g}/\text{ml}$. for 5 h before enzyme treatment, and 250 $\mu\text{g}/\text{ml}$. after treatment until the time of fixation.

A suitable time after exposure to enzyme (23–27 h) cultures were treated with colchicine (0.8 $\mu\text{g}/\text{ml}$.) for 3–5 h. The cells were suspended by trypsinization, treated with hypotonic solution (0.075 M KCl)⁷, fixed rapidly in methanol-acetic acid (3:1), spread on chilled slides, air-dried and stained with 1 per cent acetic-orcein. Metaphases suitable for chromosome examination were selected under low magnification and studied under oil immersion for any abnormalities. These were classified as (a) chromatid breaks, showing non-alignment or axial displacement of the broken ends, and (b) chromatid gaps, which included non-staining regions or small breaks in one chromatid; secondary constrictions were not scored. The figures in the tables are the percentages of cells examined with one or more chromatid breaks. Chromosome fragments and structural abnormalities (for example, dicentric and acentric) were rare and are not included in the tables.

As shown in Table 1, the incidence of chromatid breaks in human diploid cells treated with either pancreatic or lysosomal deoxyribonuclease was significantly higher than in control cells either untreated or exposed to Mg^{2+} -saline and MgSO_4 in the absence of enzymes. In cells exposed to pancreatic deoxyribonuclease inactivated by heating, or to the lysosomal enzyme and an inhibitor (poly A-poly U), the incidence of chromosome damage was comparable with that in the controls. Addition of hydrocortisone to the deoxyribonuclease treated cultures did not reduce the incidence of chromosome damage (Table 2). Because hydrocortisone is a well-known

stabilizer of lysosomal membranes⁸ this result makes it unlikely that endogenous lysosomal enzymes are being released by the deoxyribonuclease treatment. Further studies with an endonuclease from *E. coli* produced a relatively high incidence of chromatid breaks, whereas the exonuclease had no effect (Table 3).

The hypertonic MgSO_4 technique, originally used for introducing infectious viral nucleic acid into mammalian cells², has proved effective in facilitating the entry of deoxyribonuclease into cell monolayers. In spite of the high molarity of the MgSO_4 , this treatment alone had no observable effect on chromosomes, and the cells—although vacuolated immediately after treatment—seemed to recover completely and grow normally, in keeping with previous observations of Holland⁹, who used 2 M MgSO_4 on HeLa cells.

Table 1. INCIDENCE OF CHROMATID BREAKS IN WI 38 CELLS AFTER TREATMENT WITH VARIOUS NUCLEASES

Treatment	No. cells examined	Percentage cells with chromatid breaks
Untreated control	519	3.5

Treatment	No. cells examined	Percentage cells with chromatid breaks
Untreated control	122	2.5
Endonuclease	78	9.0
Exonuclease	73	1.4

Several factors indicate that the effects described here are attributable to exogenous enzyme rather than to activation of lysosomal or other endogenous enzyme systems. One is the uniformity of the response after introduction of the three types of endonucleases all of which attack intact strands of DNA in chromosomes, contrasted with the lack of effect with exonuclease. Second, when the enzyme was inactivated or when a selective inhibitor of the nuclease was used, the effect was absent. Third, treatment of cells with hydrocortisone did not reduce the chromatid breakage. A fourth point is that the extent of the chromatid damage is proportional to the concentration of deoxyribonuclease introduced (unpublished).

Thus when various endonucleases are introduced into mammalian cells they are not degraded in the host cell cytoplasm nor is their passage prevented by the nuclear membrane; they can enter the nucleus in an enzymically active form and produce chromosomal damage. Robbins *et al.*¹⁰ describe electron microscopical observations of the response of HeLa cells to hypertonic solutions. They report clumping of the chromatin around the nuclear periphery and partial disintegration of the nuclear membrane. Such an effect might facilitate contact between a cytoplasmic enzyme and nuclear DNA.

Comparable experiments on the biological effects of enzymes introduced into living cells include the establishment of viral infection in tissue culture cells by viral nucleic acids²; and those where ribonuclease is introduced into plant cells and amoebae¹¹. The phenomenon of metabolic cooperation¹² may involve a similar mechanism.

We suggest that if deoxyribonuclease can enter or be released into the cell nucleus at an appropriate stage of the mitotic cycle, chromosome damage may ensue. Such deoxyribonuclease might be introduced by or from microorganisms, or be an endonuclease redistributed or synthesized within the cell, for instance by effects of radiation or virus infection.

The whole question of the relationship of endonuclease action to DNA replication is of interest. Intact double-stranded DNA is not replicated until a "nick" is introduced by endonuclease, and Kornberg¹³ has reviewed evidence suggesting that replication involves sequential action of an endonuclease, a polymerase and a ligase. The accurate balancing of these enzyme activities is critical for maintaining the integrity of the genome; it therefore seems probable that excess free endonuclease may have deleterious consequences on chromosomal structure, as our results suggest.

We thank Dr G. Bernardi of the Centre pour la Recherche sur les Macromolécules, Strasbourg, for his cooperation in supplying the enzymes and polynucleotide, Miss M. F. Brice for technical assistance and Miss L. Taggart for statistical analyses.

Induction of a Mitochondrial DNA Polymerase in *Tetrahymena*

Tetrahymena pyriformis, strain GL, contains two different DNA polymerase activities—one major and one minor—which can be separated from one another by gel filtration on a 'Sephadex G-200' column¹. Exposure of *Tetrahymena* to various forms of radiation or thymine starvation during growth leads to a rapid increase in the total DNA polymerase activity^{2,3}. The appearance of this new activity is dependent on RNA and protein synthesis^{2,3}. Subsequent experiments have revealed that the rise in total DNA polymerase activity in such cells is the result solely of a marked rise (about 35-fold) in the amount of the minor of the two polymerase activities¹. The activity of the major DNA polymerase remains constant. Here we show that the induced DNA polymerase activity is associated with mitochondria, implying that the induced enzyme is a mitochondrial DNA polymerase.

Cells used for preparation of mitochondria were cultured in a complex medium⁴. DNA polymerase activity was

induced by thymine starvation⁵, as described previously². Mitochondria were prepared from the cells according to published methods^{6,7}, except that the cells were disrupted by low pressure (1,000 lb-inch⁻²) in a French press (American Instrument Co.), and that the various centrifugation steps of the homogenate were repeated several times more than indicated in these procedures. Inspection by electron microscope showed a preparation of essentially pure mitochondria which was only slightly contaminated with cilia. No nuclei could be detected. Cells treated with ethidium bromide were cultured in a defined medium⁸ (enriched with 0.02 per cent proteose peptone) in order to use low concentrations of the drug.

The activities of the two polymerases were measured in optimal conditions¹. The induced polymerase was assayed with heat-denatured DNA primer at an Mg²⁺ concentration of 12 mM, while the nuclear polymerase was measured with native DNA in the presence of 5 mM Mg²⁺. Activity is defined as c.p.m. of ³H-TTP (9.4×10^4 c.p.m./nmole) incorporated into DNA in 20 min. Specific activity is activity per 0.3 mg protein.

Table 1. LOCALIZATION OF THE INDUCED DNA POLYMERASE ACTIVITY IN TREATED CELLS

Enzyme	Activity (per cent)
Total cell extract	100
Sonicated mitochondria	72
Post mitochondrial supernatant	15

The mitochondria were isolated as described in the text. The 100,000g supernatants from the sonicated fractions were used as enzyme preparations.

In vitro DNA synthesis catalysed by the mitochondrial DNA polymerase from rat liver is very strongly inhibited by the dye ethidium bromide, while synthesis catalysed by the corresponding nuclear DNA polymerase is only slightly inhibited⁹. We have investigated the effect of ethidium bromide on DNA polymerase activities from *Tetrahymena*, and found that the induced polymerase activity from thymine starved cells is strongly inhibited by low concentrations of ethidium bromide (4 µg/ml.), whereas the polymerase activity from untreated cells is not. The strong inhibition of the induced activity by ethidium bromide is also observed if native DNA primer

Fig. 1. *In vitro* effect of ethidium bromide on the two DNA polymerase activities. The enzymes were prepared from cells grown in complex medium. One part of the cells was thymine starved; the other part was untreated. The mitochondria were isolated from both cultures and the 100,000g supernatants from the sonicated mitochondria were used as enzyme preparations. The ethidium bromide was incubated for 5 min with the incubation mixture before the enzyme was added. ●, Mitochondrial enzyme from untreated control cells; ○, mitochondrial enzyme from thymine starved cells; Δ, post mitochondrial supernatant from untreated cells.

Fig. 2. *In vivo* effect of ethidium bromide on the specific activity of the total DNA polymerase activity. The cells were treated with the indicated concentration of ethidium bromide for 26 h. The 100,000g supernatants were used as enzyme preparations.

is used instead of heat-denatured DNA. Thus the induced polymerase activity is similar to that of mitochondrial rat liver DNA polymerase in response to ethidium bromide. In addition, other properties, such as very high salt optimum for DNA synthesis, are identical for the two enzymes, further indicating that the induced enzyme is probably mitochondrial^{1,10}. We therefore purified mitochondria from thymine starved cells in addition to assaying the various fractions for the induced polymerase activity. Table 1 indicates that the induced activity is purified together with the mitochondrial fraction. In addition isolated nuclei do not contain significant activity (unpublished observations of M. Ikeda and O. W.). Thus we conclude that the induced DNA polymerase in *Tetrahymena* is associated with mitochondria and infer that the induced enzyme is a mitochondrial DNA polymerase. At present we cannot decide whether a new mitochondrial DNA polymerase is synthesized or whether the induced activity is the result of increased synthesis of the DNA polymerase normally present in the mitochondria of *Tetrahymena*. Polymerase isolated from mitochondria of untreated control cells is, however, inhibited by ethidium bromide to the same extent as the induced polymerase isolated from mitochondria of thymine starved cells (Fig. 1).

Both ethidium bromide and acriflavin cause cytoplasmic mutations in certain organisms¹¹⁻¹⁴. At low concentrations of the dyes this mutagenic process seems specific in that only cytoplasmic mutations occur; no nuclear mutations are observed. This indicates that ethidium bromide in such conditions interacts preferably with mitochondrial DNA. Fig. 2 shows that DNA polymerase activity is induced in *Tetrahymena* grown in the presence of low concentrations of ethidium bromide, which might imply that interference with mitochondrial DNA only is sufficient to induce a mitochondrial polymerase. The fact that the induction is completely inhibited by cycloheximide² but not by chloramphenicol (unpublished observations of O. W.) suggests that the induced polymerase is presumably under nuclear control. Thus the system described here might be a potentially useful one for studying nuclear and mitochondrial interaction.

Adenine-rich Polymer associated with Rabbit Reticulocyte Messenger RNA

POLYPURINES have been isolated from subcellular fractions of mouse liver by a method which involves a limited nuclease digestion of the RNA, followed by chromatography of the digestion products on polystyrene columns¹⁻³. These polypurines consist of clusters of adenylic acid and guanylic acid in which the A/G ratio is 2-10; the materials isolated from the rough endoplasmic reticulum have sedimentation coefficients of 3-5S, but a molecule containing twenty nucleotides can be obtained from the free polysomes⁴. The latter polymer is part of a rapidly labelled RNA species that sediments between the 32S subunit and 5S RNA when EDTA-treated polysomes are centrifuged on a sucrose density gradient. With longer times of labelling with ³²P the polymer is also found in association with the 32S subunit. It seems likely that the adenine-rich polymer is found in close association with messenger-like RNA. These observations prompted us to investigate the polypurine content of a better characterized mammalian messenger RNA. Such an RNA is the haemoglobin messenger RNA which has been isolated from rabbit reticulocytes^{5,6}, and purified by polyacrylamide gel electrophoresis⁷. This species of RNA⁸ and a similar RNA from mouse reticulocytes⁹ have been demonstrated to initiate specific globin synthesis *in vitro*. We now describe the isolation of an adenine-rich polymer from purified messenger RNA obtained from rabbit reticulocyte polysomes and its relationship to the size of the ribosomes from which the messenger RNA is derived.

Ribosomal subunits and the messenger RNA-protein complex¹⁰ were obtained from rabbit reticulocytes essentially as described by Labrie⁷. The different fractions, adjusted to contain 0.1 M Tris-HCl (pH 9.0) and 0.2 per cent sodium dodecyl sulphate (SDS), were extracted at room temperature with an equal volume of distilled phenol previously equilibrated with the same Tris-SDS buffer^{1,3}. The aqueous phase was re-extracted with one-half its volume of the phenol and, after the addition of 0.2 M sodium acetate-acetic acid buffer to adjust the pH to 5, the RNA was precipitated with 2.5 volumes of ethanol at -20° C. After repeated washings with ethanol and finally ether, the RNA was dissolved in 0.03 M Tris-HCl (pH 7.6) containing 0.001 M EDTA and 10 per cent sucrose and subjected to electrophoresis on 2.5 per cent polyacrylamide gels¹¹.

RNA from the 50S subunit was predominantly of the 29S type and included an 18S as well as a 5S peak (Fig. 1a); that from the 30S subunit was predominantly 18S (b). The RNA from the messenger RNA-protein complex showed the presence of a major 10S peak as well as 29S, 18S, 5S and 4S peaks (c). Intermediate RNA species were also present. The specific activity of the 10S messenger RNA was always found to be at least four times higher than that of any other species except 4S RNA.

RNA from the peaks of the different principal species was extracted from the gel slices by homogenizing the gel in 0.1 M NaCl-0.05 M Tris (pH 8.9). The extracted RNA was dialysed against 0.01 M Tris-HCl (pH 7.6) and then incubated with 2 µg ribonuclease S and 16 µg deoxyribonuclease per ml. in 5 × 10⁻³ M MgSO₄ at 37° C for 15 min. After inactivation of the ribonuclease with trypsin, the solution in 0.2 M sodium phosphate (pH 7.6) was applied to polystyrene columns. These retain ribonuclease-resistant polypurines while digested products are eluted by the phosphate buffer^{1,3}. Subsequent elution with phosphate buffer containing 2 mg/ml. of SDS quantita-

Fig. 1. Electrophoretic analysis of RNA extracted from (a) 50S, (b) 30S subunits and (c) messenger RNA-protein complex of rabbit reticulocyte polysomes. Reticulocytes were obtained from rabbits 18 h after injection of 40 mCi of ³²P-orthophosphate. Electrophoresis was performed at 3.5 mA per tube for 2.5 h at 0-4° C on 2.5 per cent gels. Gels fixed in 4 per cent acetic acid were scanned at 260 nm in a Gilford gel-scanner attached to a Beckman recording spectrophotometer. Gel slices were assayed for radioactivity by measurement of Cerenkov radiation¹² in this and subsequent figures. —, A_{260} ; ●, radioactivity.

tively clutes the polypurines (SDS fraction). This showed that 10 per cent of the counts in the 10S RNA were present as polypurines in the SDS fraction, while the 29S and 18S RNAs had no significant content of these purine-rich polynucleotides. The nucleotide composition of the ribonuclease-resistant component of the 10S RNA was determined by measurements of ^{32}P radioactivity and its size estimated by electrophoresis on 10 per cent polyacrylamide gels (Fig. 2).

The results demonstrated that 10S RNA contained a component with an AMP content of over 70 per cent, contributing 10 per cent of the total radioactivity of the messenger RNA. This adenine-rich cluster was shown to be present in a range of sizes of 50–70 nucleotides on the basis of its mobility compared with that of 4S RNA. An adenine-rich cluster of this size is compatible with the observation by Labrie⁷ that the 10S RNA, containing about 550 nucleotides, had an excess of 75–125 nucleotides over the number required for the coding of either of the two globin chains, and that the extra nucleotides were probably at one end of the messenger RNA molecule. Also consistent with our results is the earlier observation¹⁶ that the nucleotide composition of the messenger RNA determined by ^{32}P analysis showed higher values for AMP than that obtained by spectrophotometric analysis. This discrepancy in values could be explained by a sequence of adenylic acids whose precursor (ATP) had a higher specific activity than the other nucleotides. Another explanation would be that newly synthesized ^{32}P -labelled messenger RNA had a more extensive adenine-rich cluster than the pre-existing messenger RNA and that the adenine-rich cluster was being degraded at a higher rate than the rest of the messenger RNA.

^{32}P -labelled reticulocytes were lysed by the addition of an equal volume of 0.005 M MgCl_2 . Sucrose density gradient centrifugation of the reticulocyte polysomes from the lysate was performed as described by Rich¹⁷. A graded selection of the various aggregates of ribosomes was obtained and RNA extracted from these separate fractions. The RNA of each fraction was then subjected to electrophoresis on 5 per cent polyacrylamide gels which permits selection of the messenger RNA without a previous separation of the subunits. Electrophoretic analysis of the RNA demonstrated clearly the high levels

Fig. 2. Characterization of the ribonuclease resistant purine-rich fraction of 10S RNA. Part of this fraction was hydrolysed with 0.3 M LiOH for 18 h at 37°C and after removal of lithium as the perchlorate salt with isopropanol-ether^{3,13} the nucleotides were separated by high voltage electrophoresis¹⁴. The nucleotide composition was: AMP, 70.3; GMP, 11.9; CMP, 3.8; UMP, 14.0. Another part was subjected to electrophoresis in a 10 per cent polyacrylamide gel using 4S RNA as a marker^{14,15} at a current of 5 mA/tube at $0-4^\circ\text{C}$. —, A_{260} ; ● · · · ●, radioactivity.

Fig. 3. Separation of 10S RNA of a fraction derived from a sucrose density gradient of ^{32}P -labelled polysomes. Similar analyses were obtained with three other fractions derived from the polysomes on the basis of size. Electrophoresis was performed at $0-4^\circ\text{C}$ on 5 per cent polyacrylamide gels for 2 h, at 4 mA/tube. —, A_{260} ; ● · · · ●, radioactivity.

of radioactivity contributed by the sharp peak corresponding to the 10S RNA compared with that of 4S and 5S RNAs. 18S RNA barely penetrated the gel in the conditions of electrophoresis (Fig. 3). The highly labelled 10S RNA was extracted by homogenization in 0.1 M sodium acetate (pH 7.9) and the RNA precipitated from the high salt medium by cetyl trimethylammonium bromide (CTA)¹⁸. The RNA was converted to the sodium salt and digested with ribonuclease S and deoxyribonuclease as before and the products were separated by polystyrene chromatography to obtain the adenine-rich polymer. After the removal of the SDS by precipitation with KCl, about one A_{260} unit of 4S RNA was added and the RNA was precipitated with CTA. The use of CTA resulted in quantitative recovery of the radioactivity and the RNA samples were then separated on 10 per cent polyacrylamide gels.

Fig. 4 shows that the proportion of the adenine-rich polymer in the various 10S messenger RNAs decreased when the messenger RNA was derived from lighter polysomes or monosomes. This was also reflected as a gradual but definite decrease in the size distribution of the adenine-rich polymer when the messenger RNA was obtained from aggregates of diminishing size, being smallest when obtained from monosomes. It seems as if there is a direct relationship between the size of the adenine-rich polymer and that of the aggregate of ribosomes from which the parent 10S messenger RNA is derived.

The process of maturation of the mammalian reticulocyte is accompanied by a diminishing capacity to synthesize protein and by a progressive loss in ribosomal content, reflected in a decrease in the proportion of larger polysomes in the older cells¹⁹⁻²¹. Accordingly, in a reticulocyte lysate containing the ribosomal contents of a mixed population of maturing reticulocytes, more larger polysomes would be expected to be derived from younger cells and more of the monomers and dimers from older cells, although a considerable overlap would exist. Because the messenger RNA from the larger polysomes has more adenine-rich clusters than the messenger RNA from the smaller polysomes, this variation might be a reflexion of the comparative age of the messenger RNA. The adenine-rich clusters could represent non-translatable residues

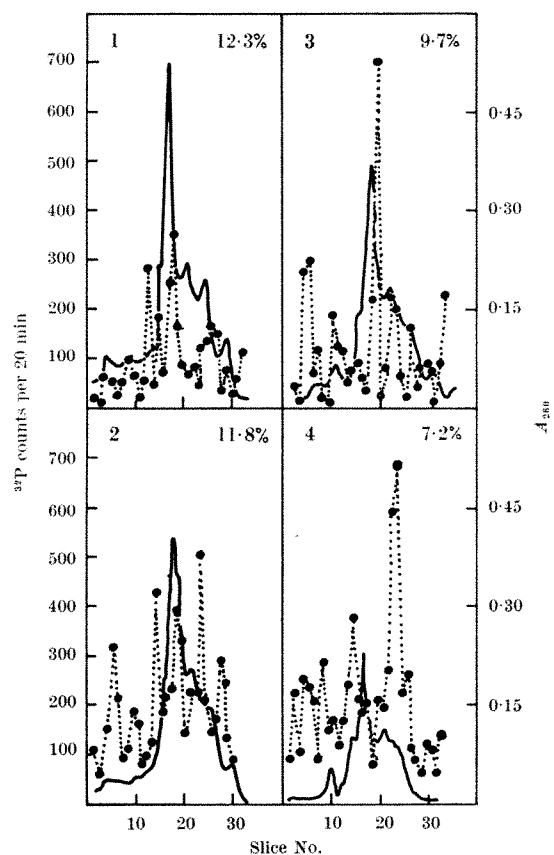

Fig. 4. Electrophoretic analyses of the polypurines of the 10S RNA extracted from the different regions of the polysomes. (1) Polypurines derived from the messenger RNA of the heaviest polysomes; (2) and (3) represent the polypurines of messenger RNA of progressively lighter polysomes; (4) polypurines of the messenger RNA of a fraction consisting mainly of monosomes. The 10 per cent gels were subjected to a current of 5 mA/tube for 90 min at 0–4° C. The proportion of the polypurines in the 10S RNA fraction is shown at top right and expressed as a percentage of the total radioactivity in the 10S RNA fraction from which the polypurines were derived. —, A_{260} ; ●, radioactivity.

that are involved in defining the extent of utilization of the messenger RNA, portions of these adenine-rich clusters being removed successively in each round of the translation process. A similar scheme has been proposed recently by Sussman²² on the basis of entirely different observations. Studies are in progress to determine the fate of these clusters during translation and also to ascertain at which end of the messenger RNA these adenine-rich clusters are located, should they prove to be an integral portion of the messenger RNA.

Evidence for Immunological Identity of Human and Simian (Baboon) TSH in Serum

IMMUNOLOGICAL cross-reaction as determined by radioimmunoassay has been demonstrated between human and simian growth hormones¹, and between human and simian chorionic gonadotropin². By contrast, there was no evidence of such identity between human and simian luteinizing hormones or follicle stimulating hormones³. Corresponding observations on human and simian TSH have not been reported, but we now present evidence for very close and probably identical immunological cross-reaction between human and baboon TSH on the basis of radioimmunoassay.

Because purified simian TSH is not available, our investigation depended, first, on a comparative study of the changing levels of immunoassayable TSH in human and baboon sera in varying conditions of thyroid hormone excess or deficiency; and, second, on a parallel study of the inhibition curves produced in the immunoassay by the standard preparation of human TSH and by serial dilutions of serum containing high endogenous levels of TSH from hypothyroid human subjects and baboons. The parallelism between these inhibition curves and by serial serum dilutions in these conditions, and with a specific immunoassay, strongly suggests immunological identity.

The radioimmunoassay of human TSH (HTSH) used in these studies is essentially as described previously⁴. HTSH (the gift of the National Pituitary Agency, Endocrinology Study Section, and National Institute of Arthritis and Metabolic Diseases) is labelled with ¹²⁵I (Iso/Serv Division, Cambridge Nuclear Corporation) using the method of Hunter and Greenwood⁵. The antiserum now being used was raised in a rabbit immunized by a single intrasplenic injection of a purified preparation of HTSH in emulsified Freund's adjuvant. It binds 40–50 per cent of a 25 pg label at a final dilution of 1 : 300,000, and cross-

Fig. 1. Inhibition curves in the HTSH radioimmunoassay (¹²⁵I-HTSH, 25 pg; anti HTSH, final dilution 1 : 300,000) produced by HTSH (MRC research standard A) (○), HFHSH (MRC research standard A) (●), HLH (MRC research standard A) (△), LER 907 (human pituitary gonadotropin reference preparation) (▲), and HCG (8,700 IU/mg, Ortho Research Foundation) (□).

reacts with MRC reference preparations of human FSH (HFSH) and human LH (HLH) only at very high and supra-physiological concentrations of these two hormones (Fig. 1). (The observed cross-reaction produced by these reference preparations and by the pituitary gonadotropin reference standard LER 907 may arise in part from contamination with variable amounts of HTSH known to be present in these materials.) Cross-reaction with human chorionic gonadotropin (HCG) does not occur (Fig. 1). This antiserum is now available from the Division of Biological Standards, National Institute for Medical Research, London. All serum levels of TSH are reported with respect to the MRC research standard A HTSH (the gift of Dr Derek Bangham). Separation of antibody-bound and free labelled hormone is carried out using a modification of the dextran-coated charcoal procedure⁶. The assay is sensitive down to 2.0 μ units HTSH/ml. of serum.

Fig. 2. Serial observations of serum thyroxine and TSH levels in two human subjects in varying conditions of thyroid hormone excess and deficiency.

Fig. 3. Serial observations of serum thyroxine and TSH levels in two baboons in varying conditions of thyroid hormone excess and deficiency.

Fig. 4. Inhibition curves in the HTSH radioimmunoassay produced by the HTSH standard and serial dilutions of various human and baboon sera.

Serial measurements of serum levels of TSH and thyroxine iodine (by column chromatography, performed by the Division of Nuclear Medicine, Toronto General Hospital, and by Bio-Science Laboratories, Van Nuys, California) have been made in human subjects and baboons in the following situations: (a) in a patient with hyperthyroidism due to Graves's disease who was treated with radioiodine, subsequently became hypothyroid, and was then restored to a euthyroid state by thyroxine administration; (b) in a patient with primary hypothyroidism who was made euthyroid and then mildly hyperthyroid by thyroid hormone replacement therapy; (c) in two baboons, one male and one female, which became hypothyroid following surgical thyroidectomy, one of these animals subsequently being made hyperthyroid by thyroid hormone replacement, and then again allowed to become hypothyroid following withdrawal of therapy. Additional studies were performed on sera obtained from two adult patients with Klinefelter's syndrome, one adult patient with Turner's syndrome and one postmenopausal woman, none of whom was receiving any form of hormonal replacement therapy. Each of these clinical conditions has been shown to be characterized by high serum levels of pituitary gonadotropins as determined by radioimmunoassays for HFSH and HLH^{7,8}. Serum was also obtained from a baboon ovariectomized two years previously and given no hormonal replacement. It was assumed—no specific assay being available for determination of baboon FSH and LH—that this serum would also contain high levels of pituitary gonadotropins.

Serial determinations of TSH and thyroxine levels in the sera of the two human subjects and the two baboons before and following various forms of therapy are shown in Figs. 2 and 3, respectively. In each case a fall in serum thyroxine is accompanied by a rise in immunoassayable TSH, and vice versa; and a rise in the thyroxine level results in a decrease of serum TSH, often to levels below the minimal sensitivity of this assay. From the baboon studies it seems probable that a considerable time is required (> 2 months) for serum TSH levels to reach a maximum in response to prolonged hypothyroxinaemia. The absolute levels of immunoassayable TSH in the human subjects and in the baboons seem to be comparable in all the conditions of these studies.

Serial dilutions of serum from a hypothyroid human subject and a hypothyroid baboon produced identical inhibition curves in the HTSH immunoassay which were identical

to that for the HTSH standard hormone (Fig. 4). By contrast, no inhibition of the binding of the labelled HTSH to the antiserum was produced either by an equally wide range of serial dilutions of serum from patients with conditions associated with high levels of circulating pituitary gonadotropins, or when serial dilutions of serum were assayed from the ovariectomized baboon (Fig. 4).

We conclude (1) that endogenous TSH in the serum of human subjects and baboons cross-reacts identically in the radioimmunoassay for HTSH; (2) that absolute levels of TSH measured in the serum of humans and baboons by this assay system seem to be similar, and change almost identically with changing concentrations of serum thyroxine; and (3) that FSH and LH present in the serum at presumed high concentration in both humans and baboons do not cross-react in this radioimmunoassay for HTSH.

These studies were supported by grants from the Medical Research Council of Canada and the US National Institutes of Health.

Follicle Stimulating Hormone Releasing Activity in Hypophysial Portal Blood and Elevation by Dopamine

FSH-releasing activity, which has been attributed to an FSH-releasing factor (FRF), has been found in hypothalamic tissue¹⁻⁵. It has been assumed that FRF reaches the anterior pituitary through the portal vessels of the hypophysial stalk, but this has not yet been observed in the blood of the portal vessels.

Sawyer *et al.* suggested that neurotransmitter substances are involved in the control of ovulation⁶. Subsequently, many studies have confirmed that the depletion of brain monoamine by reserpine⁷ and the inhibition of catecholamine synthesis^{8,9} prevent ovulation. Moreover, the phenomena of the oestrous cycle, castration, pregnancy or pseudo-pregnancy, which are associated with changes in the levels of sex steroids in the blood, are correlated with changes in the amount of monoamine and the activity of monoamine oxidase in the basal hypothalamus¹⁰⁻¹³. It has been shown that monoamines are present in large amounts in several regions of the mammalian brain and that adrenergic nerve terminals are especially dense in the tuberoinfundibular region of the hypothalamus¹³.

We have observed that there is a marked increase in the LRF activity^{14,15} and prolactin inhibiting factor (PIF) activity (ref. 16 and our unpublished work) in the plasma of the hypophysial stalk after injection of dopamine into the third ventricle of the brain of rats. Intraventricular injections of dopamine into male rats also resulted

in an increase in the plasma concentration of LH^{14,17} and of FSH¹⁸, and a decrease in the concentration of prolactin¹⁶. The infusion of dopamine directly into the anterior pituitary through a cannulated stalk portal vessel had no effect on the release of LH^{14,17}, FSH¹⁸ or prolactin¹⁶. These observations led us to test the hypothesis that dopamine may also stimulate the release of FRF into the blood of the hypophysial portal vessels.

Blood from the pituitary stalk was collected for 2-4 h from male Sprague-Dawley rats weighing 350-450 g¹⁹. For control purposes, blood was obtained simultaneously from the femoral artery of the same animals. The donors of the stalk blood were treated in one of two ways: (1) at the beginning of the collection period, one group of rats was given dopamine hydrochloride (equivalent to 2.5 µg dopamine) in 2.5 µl. of 0.15 M NaCl, the solution being injected into the third ventricle of the brain at a point midway between the optic chiasma and the anterior margin of the median eminence; (2) in another group of animals, the injection was omitted.

Blood plasma from 10 to 12 similarly treated rats was combined, and portions were assayed *in vitro* for FSH-releasing activity. Anterior pituitaries from animals killed by decapitation were bisected along the midline. One pituitary half served as the control, and the contralateral half served as the experimental tissue. All incubations were performed under an atmosphere of 95 per cent O₂ and 5 per cent CO₂ in a metabolic shaker set for 45 rev/min and 25° C. Each pituitary half was placed in a separate flask containing 0.5 ml. of a tissue culture solution ('Difco', medium 199, pH 7.2). After 1 h, the incubation fluid was removed, and blood plasma from the femoral artery was added to one pituitary half. Plasma from the hypophysial stalk was added to the opposite half of the same gland. The incubation was continued for another hour. The quantity of FSH released into the incubation medium by each pituitary half was determined by radioimmunoassay²⁰.

The concentration of FSH in the femoral plasma was undetectable; however, stalk plasma from untreated rats and from rats treated with dopamine contained 0.21 and 0.36 µg/ml., respectively, equivalent to the NIAMD-rat-FSH-RP-1 reference preparation. These quantities were taken into account in the calculation of the results.

During the first hour, when medium 199 was the incubation fluid, the spontaneous release of FSH was 3.85 ±

Fig. 1. Effect of hypophysial stalk plasma from untreated rats on FSH release by pituitary halves *in vitro*. The number of halves is shown in parentheses. The vertical lines represent the magnitude of the standard errors.

Fig. 2. Effect of hypophyseal stalk plasma from dopamine-treated rats on FSH release by rat pituitary halves *in vitro*. The number of halves is shown in parentheses. The vertical lines represent the magnitude of the standard errors.

0.26 (mean values \pm s.e.; $N=10$) and 3.65 ± 0.26 $\mu\text{g/h}$ by one set of pituitary halves (Fig. 1) and 4.26 ± 0.24 and 4.05 ± 0.21 $\mu\text{g/h}$ by the other set (Fig. 2). When plasma was substituted for medium 199, the rates of FSH release by pituitary halves in femoral plasma were 3.45 ± 0.25 and 3.63 ± 0.26 $\mu\text{g/h}$ (Figs. 1 and 2). These rates were similar to those observed in the first hour when medium 199 was the incubation fluid. The pituitary halves incubated in stalk plasma from untreated animals released 6.34 ± 0.29 $\mu\text{g/h}$ or 1.8 times as much FSH as those incubated in femoral plasma (Fig. 1). The differences between the responses of the paired halves were statistically significant ($P < 0.001$). The halves incubated in stalk plasma from rats treated with dopamine released 19.3 ± 1.20 $\mu\text{g/h}$ or 5.3 times as much FSH as the halves incubated in femoral plasma (Fig. 2). Again, the differences between the responses of the paired samples were significant ($P < 0.001$). The quantity of FSH released by glands incubated in stalk plasma from rats treated with dopamine was also significantly greater than that released by pituitary halves incubated in stalk plasma from untreated animals (Figs. 1 and 2).

These observations show that plasma from the pituitary stalk of the rat contains FSH-releasing activity and this activity in stalk plasma is increased when dopamine is injected into the third ventricle. The FSH-releasing activity may be caused by FRF, the release of which may be regulated by a dopaminergic mechanism.

We thank Mrs Jane C. Gottwald for help in the preparation of the manuscript; and the National Institute of Arthritis and Metabolic Diseases, Rat Pituitary Hormone Program, for the reagents used in the radioimmunoassay of FSH. This research was supported by grants from the National Institutes of Health and the Population Council.

4-Threonine-Oxytocin: A More Active and Specific Oxytocic Agent than Oxytocin

SINCE the original synthesis of oxytocin¹, the principal uterine contracting and milk ejecting hormone of the posterior pituitary gland, more than 200 analogues have been synthesized in a number of laboratories and the structure-function relationships of the parent hormone have been elucidated pharmacologically². We now wish to report the synthesis and properties of 4-threonine-oxytocin, an analogue of oxytocin in which the glutamine residue in the four position is replaced by a threonine residue. This analogue has strikingly greater activities in the isolated rat uterus and fowl vasodepressor assays than oxytocin itself, and possesses specifically weaker vasopressor and antidiuretic activities than oxytocin. We believe that study of this analogue may help (a) in elucidating the nature of hormone-receptor interactions, (b) from the standpoint of the phylogeny of the neurohypophyseal hormones, and (c) in clinical use.

The key intermediate required for the synthesis of 4-threonine-oxytocin was the protected nonapeptide, N-benzylloxycarbonyl-S-benzyl-L-cysteinyl-O-benzyl-L-tyrosyl-L-isoleucyl-O-benzyl-L-threonyl-L-asparaginyl-S-benzyl-L-cysteinyl-L-propyl-L-leucyl-glycinamide. This protected nonapeptide was synthesized by the solid phase method³, essentially following the procedure for the synthesis of oxytocin⁴ and 8-phenylalanine-oxytocin⁵. It had a melting point of 240° – 242° C and an optical rotation $[\alpha]_D^{25} -27.5^{\circ}$ ($c=1.0$, dimethylformamide). The amino-acid composition of an acid hydrolysate was Asp₁₋₀₁, Thr₀₋₉₂, Pro₁₋₀₅, Gly₁₋₀₀, Ile₀₋₅₅, Leu₁₋₀₅, Tyr₀₋₇₆, S-benzyl-cysteine, 1.96; ammonia, 2.15. Conversion of this intermediate into 4-threonine-oxytocin was effected as described previously in 4-6; $[\alpha]_D^{25} -10.4^{\circ}$ ($c=0.5$, 1M acetic acid); amino-acid ratios composition: Asp₁₋₁₂, Thr₁₋₀₅, Pro₁₋₀₈, Gly₁₋₀₀, Cys₂₋₁₀, Ole₁₋₀₀, Leu₁₋₁₃, Tyr₁₋₀₅, (NH₃)₂₋₀₄. Thin layer chromatography and paper electrophoresis of the purified material indicated that it was homogeneous. Assay of the 4-threonine-oxytocin by several methods⁷ gave the values indicated in Table 1 and more complete details of the synthesis and pharmacological evaluation will be published elsewhere.

Our pharmacological data clearly differentiate 4-threonine-oxytocin from any reported analogue of oxytocin

Table 1. PHARMACOLOGICAL ACTIVITIES (IN USP UNITS PER mg) OF OXYTOCIN, 4-THREONINE-OXYTOCIN, AND THREE OTHER 4-SUBSTITUTED ANALOGUES OF OXYTOCIN

Oxytocin and analogues	Rat uterus	Fowl vaso-depressor	Rabbit milk ejection	Rat vaso-pressor	Rat anti-diuretic
Oxytocin ²	450	450	450	5	5
4-Threonine-oxytocin	900	1,480	540 (rat = 530)	0.43	3
4-Serine-oxytocin ²	195	230	255	0.1	0.06
4- α -Aminobutyric acid-oxytocin ²	72	108	225	0.1	0.2
4-Valine-oxytocin ⁸	139	230	419	0.005	0.5

solely on the basis of its high oxytocic and fowl vaso-depressor activities and relatively low antidiuretic activity. It is instructive to compare the pharmacological properties of 4-threonine-oxytocin with those of three other 4-substituted oxytocin analogues: 4-serine-oxytocin², 4- α -aminobutyric acid-oxytocin² and 4-valine-oxytocin⁸ (Table 1). 4-Threonine-oxytocin is clearly the most potent and yet this difference must be accounted for by very minor structural differences in the side-chains of the four amino-acids involved: serine, threonine, α -aminobutyric acid and valine. The presence of both the methyl and hydroxyl groups on the β -carbon atom of threonine must be essential for the enhanced activity.

4-Threonine-oxytocin is both more active and more specific than oxytocin in its effects on the rat uterus, and is at least as effective on mammary myoepithelial cells. Thus it has more of the desired physiological properties of an oxytocic hormone and less vasopressin-like activities. If 4-threonine-oxytocin had appeared by mutation during mammalian phylogeny it might be expected to have sufficient adaptive value to survive. It might even occur in some mammalian species, in which case it would not be the first example of a neurohypophysial peptide that was synthesized before its natural existence was recognized: both arginine-vasotocin⁹ and mesotocin¹⁰ were synthesized first and later identified as neurohypophysial hormones.

The course of evolution of neurohypophysial peptides is not clear. Two main lines may have diverged early in vertebrate phylogeny: one contains the 4-serine peptides (glutitocin and isotocin); the other, the 4-glutamine peptides¹¹. A mutation from serine to threonine requires one nucleic-acid base change (UCA/UCG to ACA/ACG). Serine-containing neurohypophysial peptides are only known to occur among cartilaginous and actinopterygian fishes, however, and may not have been present during any stage in the evolution of mammals. A mutation from glutamine to threonine, as would have to occur in the evolution of 4-threonine-oxytocin from oxytocin, requires two base changes, with an intermediate lysine or proline step. Both 4-lysine and 4-proline analogues are very weakly active and would be ineffective oxytocic hormones¹². Thus although 4-threonine-oxytocin might have adaptive advantages as a mammalian oxytocic hormone, it may never have evolved because of the deleterious nature of the necessary mutation.

Clinically the high oxytocic and low antidiuretic activities may give 4-threonine-oxytocin a distinct advantage over oxytocin, assuming that the analogue has similar oxytocic specificity in women. When oxytocin is infused to induce labour, its intrinsic antidiuretic activity causes water retention and, if the infusion is prolonged, may precipitate acute water intoxication. 4-Threonine-oxytocin might be safer.

Deamino oxytocin¹³, an analogue in which the N-terminal amino group is replaced by a hydrogen atom, is also a more potent oxytocic agent than oxytocin. It does not, however, have the same degree of selectivity as 4-threonine-oxytocin, because the antidiuretic potency is also intensified. To our knowledge, this is the first report of the enhancement of activity of a natural peptide hormone by the replacement of a single L-amino-acid.

We thank Mrs Esther Coy for technical assistance, Mrs Sara Crumm and Dr Ting-chi Wu for the amino-

acid analyses, and Mrs Margot Acosta for performing the bioassays. This work was partly supported by the Medical College of Ohio and by grants from the National Science Foundation and the National Institute for Arthritis and Metabolic Diseases, US Public Health Service.

Protected Intermediate for the Preparation of Semisynthetic Insulins

PORCINE insulin has only three amino groups, those of the terminal residues of the two chains (glycine^{A1}, phenylalanine^{B1}) and a side chain amino group (lysine^{B29})¹. Many reagents have been developed to take advantage of the reactivity of the NH₂ group in proteins—probably more than for any other functional group—and there have been many reports on the modification of insulin activity by such reagents. Our approach is part of an attempt to develop and use methods which make it unnecessary to synthesize a whole protein when a structure is required which departs only slightly from a naturally occurring one². In the present application to insulin it resembles that of Brandenburg and Ooms³, who used Edman's phenylisothiocyanate (PITC) method⁴ to attack and remove the amino terminal residues of both chains and subsequently coupled an amino-acid back in their place. In this way residues A1 and B1 had both to be replaced with the same amino-acid (glycine). In the course of the procedure, lysine^{B29} was (irreversibly) protected by acetylation.

We report here the use of PITC for specific blocking of one of the α -amino groups as the phenylthiocarbamyl (PTC-) derivative followed by reversible protection of the other two amino groups by the trifluoroacetyl (TFA-) group. The resulting totally amino protected insulin (mono-PTC-, di-TFA-derivatives) can then be treated with anhydrous trifluoroacetic acid (TFA) to remove the PTC-protected residue without affecting the other two protected groups. The value of such a product is that it represents the first requirement in the preparation of many modified insulins. The replacement of amino-acids can involve a different amino-acid, or one substituted isotopically or by a heavy element, or an analogue. Alternatively PITC and TFA can be used to remove the next residue, again without affecting the rest of the molecule, and so on for several

more cycles. Material obtained by more than one cycle of the Edman procedure would offer greater flexibility in resynthesis, for peptides and peptide derivatives could be coupled back, as well as making possible a study on the influence of stepwise removal of residues on biological activity. We have prepared one of the two possible products fulfilling these requirements: [des-Phe^{B1},TFA-Gly^{A1},TFA-Lys^{B29}]-insulin (valine^{B3} with free αNH_2 group) and have made preliminary use of it to bring about a substitution at the amino terminus. The fact that the disulphide bridges have been kept intact throughout places severe constraints on the range of reaction conditions that one can use, but we consider that the freedom from the necessity to re-combine the chains more than justifies the extra effort.

The preparation and use of the derivative take place in a number of stages. First, insulin is reacted with PITC and the required mono-PTC-derivative separated from the other reaction products. The remaining amino groups are then protected and the PTC-residue is removed by cyclization to the phenylthiohydantoin in anhydrous TFA. Replacement of the residue which has been removed is then effected by reaction with an amino-acid activated ester. At all stages it is necessary to be able, if required, to separate derivatives which differ by the number of amino groups acylated and to have a rapid diagnostic method to assess the extent of the reactions. The first need is met by chromatography on DEAE-cellulose in 7 M urea (Fig. 1) and the second by isoelectric focusing in acrylamide gel⁶ (Fig. 2). Finally, solvents must be found in which the desired processes can be carried out without irreversible denaturation of the protein.

The reaction with PITC and the separation of the mono-derivative are described in Fig. 1. Reversible protection of the other two amino groups gives rise to two problems. First, it is essential that the protecting group chosen should be completely stable to strong acid conditions (particularly if the Edman procedure is to be repeated for a number of cycles). Second—a common problem in semi-synthetic work—methods of protection developed for the side chains of free amino-acids are frequently too severe for use in a protein. We considered two possibilities, the phthaloyl group and the trifluoroacetyl group. N-Carboethoxyphthalimide⁷ was found to react with the amino groups of insulin in mild aqueous conditions and was not removed by anhydrous TFA after 45 min at 20° C.

Fig. 1. DEAE-cellulose chromatography at 2° C of the rotary-evaporated products of the Edman reaction in the autotitrator. Insulin (1 g) was dissolved in 100 ml. 1 per cent NaCl at pH 9.5, 40° C, by addition of NaOH. The pH was adjusted to 8.5, 150 μl . of redistilled PITC added and the pH kept constant by the addition of 0.2 M NaOH in an autotitrator. When 175 μl . of the NaOH had been taken up (about 1 h), the reaction was stopped by adjustment to pH 5.3 and the precipitate was washed, collected and dried. This gives rise to a mixture of insulin, mono-PTC-derivative (about 85 per cent on phenylalanine^{B1} and 15 per cent on glycine^{A1}), di-PTC-derivative (almost exclusively on the $\alpha\text{-NH}_2$ groups) and tri-PTC-derivative (peaks 0–3 respectively). Alternatively, particularly if the glycine^{A1} monoderivative is not required, the conditions of Brandenburg⁸ can be used. Here the solvent is pyridine-water (3 : 1) and pH is not controlled. Kinetic studies, monitored by the isoelectric focusing technique, show that the optimum time for production of monoderivative is between 8 and 22 h. 65 g dry weight of exchanger was used in a column of 1.8 cm internal diameter. Flow rate was 40 ml/h. The starting eluent was 0.01 M Tris-0.001 M EDTA-0.03 M NaCl-6.95 M urea (pH 7.7, 20° C). The gradient was linear to 0.1 M NaCl in the same solution. Total eluted volume was 3 l. Better purification of the PTC-phenylalanine^{B1} monoderivative can be achieved by rechromatography of the relevant peak in the starting buffer without a gradient. All such materials are recovered after chromatography by adjustment to pH 5.5, dialysis at 2° C in Visking tubing (18/32 inch) and lyophilization. The identity of the product was established by amino-acid analysis, end group determination (before and after cyclization) and isoelectric focusing.

Fig. 2. Isoelectric focusing by the method of Wrigley⁹, pH 5–7. The faint line (above band 3) is found in all gels containing any protein. a, An artificial mixture of insulin (band 0), mono-TFA-derivative (band 1), di-TFA-derivative (band 2), tri-TFA derivative (band 3); b, purified porcine insulin, showing what are presumably small quantities of des-amido-insulin; c, PTC-Phe^{B1}-insulin; d, product of trifluoroacetylation of c; e, the product in d after cyclization; f, the product in e after coupling; g, the product in f after removal of protecting group.

Unfortunately, in our hands attempted removal of the group by hydrazinolysis in a variety of conditions^{8,9} did not give an adequate yield of deprotected insulin in an undegraded state.

The standard reagent for the application of the trifluoroacetyl group is ethyl thiotrifluoroacetate^{10,11}, but this will not be suitable in the case of insulin because of the attack on the disulphide bridges by the ethane thiol liberated in the protection reaction. Of the alternative trifluoroacetyl esters, phenyl trifluoroacetate¹² seemed most satisfactory. In a typical reaction, 40 mg of purified PTC-phenylalanine^{B1}-insulin was dissolved or suspended in 4 ml. of 0.01 M HCl. 60 ml. of redistilled dimethylformamide (DMF) was added and the water removed by rotary evaporation (0.2 mm Hg, 27° C) of the resulting clear solution to 20 ml. (Insulin and its derivatives frequently will not dissolve directly in anhydrous DMF.) A further 80 ml. of DMF was occasionally added at this point. 1 g of MgO was added to control the reaction and finally 2 ml. of the phenyltrifluoroacetate. The reaction, which appeared to go to completion (Fig. 2), took place for 3 h at 20° C with stirring. After removal of the MgO the protein was recovered by precipitation with ether followed by two ether washes and drying in air.

The complete stability of the TFA-groups to anhydrous TFA was established by exposing tri-TFA-insulin to TFA for 2 h at room temperature. The cyclization of the PTC-group in the TFA-protected derivative was carried out in anhydrous TFA (5 mg protein/ml.) for 1 h at 20° C. The resulting product (obtained by rotary evaporation to 15 mg/ml. and precipitation with ether) is the one sought. It can be separated from any products of partial reaction by DEAE-cellulose chromatography if necessary. If intermediates are to be stored, this is probably the best stage, for the PTC-residue is susceptible to attack by air with a resulting inability to take part in the cyclization process. For the same reason, peroxides must be eliminated from any solvents likely to contain them. The product is successfully de-trifluoroacetylated by MNH_2OH (3 mg/ml.) after 20 h at 20° C. Insulin is known¹³ not to withstand the pH of the more frequently used reagent for the removal of TFA-groups¹⁴, M piperidine (pH 12.4). Even without the rechromatography mentioned, the removal of the protecting groups yields a product forming large rhombohedral crystals of des-Phe^{B1}-insulin by the procedure of Schlichtkrull^{14,15}. There is no need for pre-treatment by extraction¹⁶ or renaturation, but, like the deprotected products of the coupling-reactions, the crystals may take some days to form. The reason for this is being investigated.

Preliminary experiments have been carried out to illustrate the use of the intermediate by reacting it with

Fig. 3. Crystals of resynthesized insulin ($\times 200$). The *tert*-butoxycarbonyl protected active ester was used in this case. Residues A1 and B29 were deprotected by 1 M NH_4OH , B1 by TFA (2 h at 20°C). The material had the correct end groups and amino-acid composition.

various amino-acid active esters. TFA-phenylalanine hydroxysuccinimide ester has been used, with and without radioactive label on the phenylalanine (^3H , 1,000 mCi/mmol). *Tert*-butoxycarbonyl-phenylalanine hydroxysuccinimide ester has also been used (see Fig. 3). Here, the *tert*-butoxycarbonyl group is not removed with the TFA-group by ammonia treatment. Because, after this treatment, the glycine^{A1} amino group is once more available for reaction while the phenylalanine^{B1} amino group is not, this may provide a more convenient route to modifications of the A chain than the accumulation of the relatively small amounts of PTC-glycine^{A1}-insulin produced in the Edman reaction.

We thank Professors D. C. Hodgkin and D. C. Phillips for encouragement and Dr J. Schlichtkrull of Novo Therapeutisk Laboratorium, Copenhagen, for gifts of insulin. Financial support was received from the British Council, the Nancy Wagon Foundation and the Medical Research Council.

New Molecular Model for the Long-range Elasticity of Elastin

THE traditional type of elastomer consists of a random network of kinetically free chains linked together by means of stable cross-links: in the case of vulcanized *Hevea*

rubber by sulphur bridges and in the case of the elastic insect protein, resilin, by di- and tri-tyrosine residues¹. The elastic force is caused by the random thermal agitation of the chains whose configurational entropy decreases with strain, while the changes in internal energy remain negligible. Some problems posed by the elastic behaviour of elastin, however, have led us to consider a fundamentally different type of elastomer.

Below 50°C the swelling of elastin in water is very dependent on temperature and the experimental difficulties to which this gives rise were overcome by Hoeve and Flory² using a mixed solvent system (ethylene glycol-water, 30 : 70) in which the swelling of elastin is almost independent of temperature. In these conditions it was found that the isometric force of a stretched piece of elastin is proportional to the absolute temperature, in agreement with the theory for rubberlike molecular networks. It has been pointed out, however, that the use of mixed solvent systems introduces a further complication, for the equilibrium distribution of the solvent components between the elastin sample and the surrounding medium is not independent of temperature³. The swelling of elastin in pure water is almost constant between 50°C and 70°C , and from mechanical measurements performed in this range of temperature it has been concluded that about 85 per cent of the isometric force is caused by changes in configurational entropy while the remaining 15 per cent is the result of changes in internal energy³.

The approach in both investigations^{2,3} is based on an application of the Wiegand and Snyder equation⁴ which presupposes not only that the system is reversible but also that it is free of chemical reactions, as discussed by Weis-Fogh⁵. The experimental results we now report indicate that elastin does not fulfil this condition and that a different approach to the problem seems to be necessary⁶.

Partridge⁷ has suggested a structural model for elastin based on electron microscopic evidence and on results obtained by gel-filtration experiments with columns filled with finely divided elastin fibres. According to this model, elastin is a two-phase system and is composed of globular molecules with the hydrophobic groups packed in the interior and the hydrophilic groups on the surface where they are exposed to the water phase which fills the space between the globules. The globules are interlinked by means of the various cross-links which have been isolated from elastin⁸⁻¹⁰. In elastin the number of amino-acid residues which carry hydrophilic side chains is unusually

Fig. 1. Structure of elastin as proposed by Partridge⁷. Corpuscular units which have a hydrophobic interior and carry hydrophilic groups on the surface are suspended in a water phase and are interlinked by covalent bonds, A when relaxed, and B when stretched by 35 per cent.

small—only 5 per cent of the total¹¹. If we assume that all the hydrophilic groups are localized at the interface, the area which they occupy is too small completely to cover the surface of the globules, assuming a molecular weight of 67,000 similar to that of tropoelastin¹². In our new functional model, the interface between globules and water should therefore contain both hydrophilic and hydrophobic groups. A diagrammatic picture of the elastin model in the relaxed and in the stretched state is shown in Fig. 1.

When such a two-phase system is strained it is possible that the restoring force is caused by a decrease in the configurational entropy of the chains, as in ordinary elastomers, and by the interfacial tension between the globules and the interglobular solvent, for any deformation of spherical globules will lead to an increased area of the interface. Such an increase in area must mean that hydrophobic groups are brought from the interior of the spheres to the surface layer where they become exposed to the surrounding water. Because transfer of hydrophobic groups from a hydrophobic environment to water is known to involve a considerable decrease in entropy of the system, in the globular structure discussed here deformations can be expected to cause a decrease in entropy larger than that found in elastomers, and which is based solely on changes in configurational entropy.

We have determined the heat exchange which occurs when small samples of purified elastin were stretched and relaxed. To decide whether elastin behaves according to the theory for rubbers or whether hydrophobic interactions could be involved, the mechanical work was compared with the heat exchange. The elastin was prepared from bovine ligamentum nuchae in the form of thin strips which were purified by repeated autoclaving according to Partridge *et al.*¹³. The microcalorimeter used was originally designed by Clarke and Rothschild¹⁴. The reaction chamber has a capacity of 2.3 ml. and an elastin sample could be suspended inside it in such a way that it could be stretched and relaxed from the outside by means of a thin silver chain. The calorimeter is suitable for measuring rates of heat production, dQ/dt , of the order of 1 mcalorie/h. When the heat production is about 3–5 mcalories and when it takes place in less than a minute after the deformation, the calorimeter can be used as an integrating device where the total amount of heat produced or absorbed,

$$Q = \int_{t=0}^t dQ/dt$$

can be estimated within about 5 per cent in the course of about 15 min. The optimal sample size is a strip 15–20 mm long and about 3 mm² in cross-section, correspond-

Fig. 2. Heat exchanges measured in the calorimeter when a sample of elastin is extended (stretched) or relaxed at room temperature in various solvents. (1) in water, (2) in 2 M methanol, (3) in 2 M ethanol, (4) in 2 M *n*-propanol, (5) in pure formamide. One division on the ordinate equals 0.046 mcalorie/min.

Table 1. HEAT EXCHANGE Q AND MECHANICAL WORK WHEN ELASTIN SAMPLES WERE EXTENDED AND RELAXED IN BUFFERED WATER AT ROOM TEMPERATURE

Sample	Mechanical work (mcalories)	$Q(\text{extend})$ (mcalories)	$Q(\text{relax})$ (mcalories)	Ratio $Q(\text{relax})/Q(\text{extend})$
1	1.33	-5.53	+5.60	1.01
2	1.02	-5.60	+6.10	1.09
		-5.71	+5.32	0.93
		-6.13	+6.00	0.98
3	1.08	-5.73	+5.50	0.96
		-5.92	+5.41	0.91

A positive sign means that heat was absorbed by the system.

ing to about 35 mg dry weight. Fig. 2 shows a typical heat response obtained on stretching and relaxing such a sample.

In a series of measurements (Table 1) it was found that the heat produced during stretching always exceeded that corresponding to the mechanical work involved. It was also almost equal to the heat absorbed when the sample was relaxed again, so that the processes are fully reversible. Because the stress-strain curves were also reversible the sample plus the surrounding solvent in the reaction chamber can be considered as a closed, reversible thermodynamic system working at constant temperature and pressure and with very small volume changes. The reversible uptake of heat, $Q^{(\text{rev})}$, is equal to $T\Delta S$, and the work done by the system on the surroundings, $W^{(\text{rev})}$, is equal to $-\Delta F$ which is the change in free energy. The fundamental equation for a closed system at constant temperature is $\Delta F = \Delta U - T\Delta S$, so that we can estimate the change in internal energy, ΔU , by inserting the two measured quantities: $\Delta U = Q^{(\text{rev})} - W^{(\text{rev})}$.

From the results in Table 1, ΔU values of between -4 and -5 mcalories are found, whereas the mechanical work corresponded to an increase in free energy of only 1.0 to 1.3 mcalories for samples stretched by 35 per cent. The results therefore indicate that deformation of elastin in water involves reversible chemical changes which are several times larger in terms of energy than the corresponding mechanical changes. In this respect elastin differs fundamentally from an ordinary rubber.

In an attempt to characterize the process further we changed the medium surrounding the sample to see if this would alter the heat exchange. It was found that changes in pH have very little effect: within the pH range 2–10 the highest value measured was 6.81 mcalories at pH 10 and the lowest value was 6.08 mcalories at pH 4, indicating that charged groups are not involved to any significant extent. Fig. 2 shows that the heat exchange is strongly influenced by the presence of organic solvents in the medium and that the effect is larger with alcohols having longer hydrocarbon chains than with those having shorter hydrocarbon chains. The heat exchange is also fully reversible in these circumstances, and it returns to its original high value when the sample is transferred back into water. The concentration of alcohol in the medium is important, as shown in Fig. 3. At ethanol concentrations exceeding 30 per cent, the entropy term changes sign so that there is a heat uptake instead of a heat output during stretching. In ethylene glycol-water (30 : 70)—the medium used by Hoeve and Flory²—the heat output was nearly equivalent to the work performed during stretching, indicating that the change in internal energy in this system is close to zero.

The effect of temperature is illustrated in Fig. 3, which shows that in water the heat of stretching decreases with increasing temperature. Again, these changes are fully reversible. Fig. 4 illustrates the pronounced shrinking of water-swollen elastin at elevated temperatures and it also shows that the stress-strain curves remain almost unchanged, indicating that the amount of work performed during a given increase in length does not alter much with temperature from 2–87°C. The change in internal energy must therefore decrease drastically with temperature because of the entropy effect. At 60°C, ΔU is about

Fig. 3. The effect of the concentration of ethanol on the heat produced when elastin is stretched at room temperature (\times — \times). The effect of temperature on the heat produced when elastin is stretched in water at pH 7 (phosphate buffer) (\circ — \circ).

Fig. 4. Length-tension curves for a sample of elastin stretched in water at different temperatures ($^{\circ}$ C).

1 mcalorie, or of the same magnitude as the mechanical work.

We conclude that the theory for rubberlike elasticity is inadequate to explain the thermodynamic behaviour of elastin, whereas it remains to be established whether the observations are compatible with the globular model—involving interfacial forces. By assuming spherical globules of a given size which are stretched into prolate spheroids of the same volume, it is possible to calculate the increase in surface area and to estimate the interfacial tension which is necessary to account for the work measured. One can also estimate the number of hydrocarbon groups which can be accommodated in the extra interface generated by the stretch and calculate the change in entropy involved in the transfer of the groups from a non-polar phase to a polar environment. Such calculations can only give the order of magnitude of the changes to be expected, because of the simplifying assumptions which are necessary, but they will show whether the corpuscular model and interfacial forces should be taken seriously or not.

On transforming a sphere into a prolate spheroid of unchanged volume, the relative increase in surface area is given by the expression $A/A_0 = \frac{1}{2}(\lambda^{-1} + \lambda^{1/2} \sin^{-1} \sqrt{1 - \lambda^{-3}} / \sqrt{1 - \lambda^{-3}})$, where A_0 is the unstrained area and λ the extension ratio (see Fig. 5). The area changes slowly at first and later it increases almost linearly with λ . If a sphere is stretched from $\lambda = 1.00$ to $\lambda = 1.35$, its surface area increases by 3 per cent. Dense protein globules of a

molecular weight of 67,000 have a diameter of about 54 Å and a surface area of about 9000 Å², so that the corresponding increase in surface area of a globule is 270 Å². The total increase in area in samples weighing 35 mg is 8,400 cm². If we assume that the total work performed during stretching (1 mcalorie) is caused entirely by this increase in surface, the necessary interfacial tension amounts to 5 dyne/cm, which seems to be reasonably small: the interfacial tension between water and diethyl ether is 10.7 dyne/cm and between water and *n*-octyl alcohol is 8.5 dyne/cm at 20 $^{\circ}$ C (ref. 15). The increase in area corresponds to the transfer of maximally 1.1×10^{-5} mole CH₃ groups from the core of the globules to the surface, each CH₃ group having a diameter of 3.7 Å. The transfer of a methyl group of an alanine side chain from a non-polar phase into water at 25 $^{\circ}$ C is accompanied by the following changes: $\Delta F_{tr} = 1.3$ kcalorie/mole and $\Delta S_{tr} = -9.4$ entropy units/mole¹⁶. In the case of the reversible transport from bulk solution into the surface we shall assume that the side chains do not become completely surrounded with water but that the actual figure amounts to half the value measured for the transfer from bulk phase to bulk phase. For the elastin samples used in this investigation we should therefore expect: $\Delta F_{tr} = 7.2$ mcalories, $T\Delta S_{tr} = -15.4$ mcalories, and $\Delta U = -8.2$ mcalories.

In other words, surface interactions between hydrophobic and hydrophilic phases can give rise to changes in entropy, free energy, and internal energy which are of the same sign and order of magnitude as those measured experimentally.

According to published figures¹⁶, an increase in temperature should result in a larger ΔF_{tr} and a numerically smaller $T\Delta S_{tr}$, so that ΔU is reduced numerically. Then interfacial interactions should contribute to the isometric force by larger amounts at the high than at the low temperatures used, whereas the heat exchange with the surroundings should decrease. This is essentially what we have found (Figs. 3 and 4).

The measurements and calculations are therefore in agreement with the hypothesis that water-swollen elastin is a two-phase system and that part of the elastic force is caused by interaction between the hydrophobic groups in the protein and the water at the interface. Part of the elastic force must, however, arise from thermal agitation of the protein chains in the interior of the globules, because in all conditions the chains must be able to move freely relative to each other and become orientated during stretching. Although we cannot yet estimate the contribution to the total stress caused by changes in configurational entropy and by surface interaction, it is worth noting that the actual force-extension curves for elastin swollen in water (Fig. 4) resemble the area-exten-

Fig. 5. The relative surface area, A/A_0 , of a sphere of constant volume which is deformed into a prolate spheroid by a unidirectional force (—) (see text). Tensile force, f , as a function of λ , as calculated for a swollen isotropic rubber according to the formula $f = Gv^{1/2}(\lambda - \lambda^{-2})$, where G is the modulus (here 6.4 kg/cm) and v the volume ratio (here 0.45) (---).

sion relationship in Fig. 5 more than they resemble the typical stress-strain curve for an ordinary rubber (broken curve in Fig. 5).

It does not seem to have been suggested before that elastomers can operate on the basis of interfacial forces, and we propose to call such an elastomer a liquid drop elastomer. In the ideal case, the interior of the drops would be completely fluid so that no orientation could be imposed on it during deformation of the droplets; the interfacial forces would be the only restoring force. The ideal case will be difficult to obtain but it should be possible to prepare synthetic elastomers of the mixed type in which both interfacial forces and changes in configurational entropy contribute to the elastic force, as suggested here for elastin.

In biology, one advantage of a liquid drop elastomer is that one can imagine the existence of elastic fibrils of much smaller diameter than is possible for rubberlike elastomers, because a single linear row of interlinked globular molecules would show an elastic behaviour which is similar to that of a larger aggregate of globules. Such elastic microfibrils could contribute to the mechanical behaviour of many cell types although their presence would be difficult to demonstrate.

We thank Mr M. J. Hubbard and Mr M. J. Pearson for assistance. This research was sponsored in part by the American Air Force through the European Office of Aerospace Research, OAR, United States Air Force, under contract.

Role of Macrophages in the Development of Immunological Maturity in Rat

MOST neonatal mammals are unable to produce antibodies after antigenic stimulation possibly because of a deficiency in a link in the chain of events which leads to the production of antibodies. The aim of this study was to ascertain the part played in the immunological immaturity of infant rats by the inability or deficiency in antibody production by macrophages.

Peritoneal cells were collected by rinsing the peritoneal cavities of adult rats without previous treatment with heparinized Parkers medium. The washings were kept ice cold and centrifuged for 5 min at 1,500 r.p.m. The cells of the sediment were counted, their viability was checked by the trypan blue exclusion test and they

were then stained for differential counting. Appropriate amounts of cells (from 12 to 36×10^6), suspended in 0.05 ml. Parkers medium with 20 per cent horse serum, were injected intraperitoneally into one day old Wistar rats; several rats of each litter, injected with the suspending medium without cells, served as controls. Two days later, all the rats (experimental and controls) were injected intraperitoneally with 0.05 ml. 20 per cent sheep red blood cells (SRBC). The peritoneal cells used for inoculation consisted of 70 per cent macrophages (60–82 per cent), 6 per cent lymphocytes (3–9 per cent) and 21 per cent granulocytes (12–30 per cent). Their viability was more than 90 per cent. Blood was drawn by heart puncture every 3–4 days, beginning from the fourth day of immunization, and the haemolysin content of the serum was determined by the micromethod of Takatsy. In several experiments, the infant rats were killed on the fourth day of immunization and their spleens were examined for plaque forming cells (PFC) after the method of Jerne modified by Sterzl. The results are shown in Table 1. The use of rats for this experiment is convenient because they do not have natural antibodies to SRBC, therefore no passive transfer of maternal antibodies can occur. Our rats can produce antibodies when twelve days old.

Table 1. ANTIBODY RESPONSE OF INFANT RATS TO SRBC AFTER INOCULATION WITH MACROPHAGES FROM ADULT RATS

* Macrophages detached after incubation on glass dishes.

Thirty of thirty-seven inoculated infant rats, which were injected with adult peritoneal cells before the antigenic stimulus, produced haemolysins in a titre of 1:4–1:512. The titre began to rise on the fourth day after the antigen and reached the peak on day 10–15. PFC (3–63/spleen) were found in the spleens of eight rats that were killed on the fourth day after the antigen. The controls which had been inoculated simultaneously with SRBC but without macrophages did not respond to the antigenic stimulus, neither by elaborating haemolysins nor PFC.

In several instances, the peritoneal cells were incubated on glass dishes, detached after 1 h with a rubber policeman and rinsed before being used to inoculate infant rats; the detached cells, devoid of non-adherent elements (that is lymphocytes and granulocytes), also induced an antibody response in infant rats.

It seems justified to assume therefore that adult, functionally adequate macrophages are the necessary prerequisite for initiating the production of antibodies to SRBC in infant rats.

Biochemical Changes during Learning in an Insect Ganglion

COCKROACHES (*Periplaneta americana*) can be mounted in such a way that when one animal places its metathoracic leg in a solution, it gets a shock at the rate of one per second. A second, control, animal gets a shock each time that the experimental animal is shocked regardless of the position of the metathoracic leg of the control animal. The experimental animal learns within 35 min to keep its leg out of the solution whereas the control animal does not learn to raise its leg, even though both animals received the same number of shocks¹⁻⁴.

We have used this system to study some of the chemical changes that take place in the metathoracic ganglion during the learning process and have compared the ganglia of experimental animals, control animals and resting animals (the latter receive no shocks). Injection of drugs such as cycloheximide⁵, acridine orange, congo red or actinomycin D slows up the learning process; the experimental animal requires more shocks and a longer time (up to 60 min) to satisfy the learning criteria. A dose-response relationship can be established between the amount of drug injected and the time that the animal requires to learn. Conversely, injection of edrophonium, prostigmine or magnesium pemolate reduced the number of shocks and time required for the animal to learn (15 min) and a corresponding dose-response relationship can be established.

The chemical changes taking place in the ganglia were studied as follows. Experimental animals were injected with ¹⁴C-uridine and the control animals with ³H-uridine immediately before the training process. Both groups of animals were then trained. After training, the metathoracic ganglia were removed, pooled and homogenized and the RNA was extracted. The carbon/tritium ratio in the RNA was determined and showed that the experimental animals had a greater incorporation of labelled uridine into their ganglionic RNA than did the control or resting animals:

Experimental > control by 44.00 ± 5.10 per cent ($n = 20$)
Control > resting by 32.25 ± 4.38 per cent ($n = 11$)
Experimental > resting by 68.80 ± 15.89 per cent ($n = 7$)

Autoradiographic studies on metathoracic ganglia showed that the experimental ganglia incorporated more radioactivity into the nerve cells at the posterior region of the ganglion, this being the region associated with leg movements⁶.

We have developed a quantitative method of estimating the distribution of labelled uridine in the experimental and control ganglia. ³H-Uridine was injected and animals were trained as described. The metathoracic ganglia were removed, dehydrated and waxed and normal histological blocks were prepared and sectioned at 20 μ m, transverse to the ganglion. Each section was placed in a vial containing scintillation fluid. The fluid dissolved away the wax and the activity in the vial was then counted. Fig. 1 illustrates a comparison of the activity in sections of the experimental ganglia and the control ganglion. The experimental ganglion incorporated more material and there was more activity in the posterior region of the ganglion, in agreement with the autoradiographic picture. Sucrose density gradient analysis of the labelled RNA in the ganglia showed that the experimental ganglia incorporated more labelled uridine into the lower molecular weight RNA fractions. The experimental ganglia also incorporated more labelled leucine than did the control or resting ganglia.

The action of drugs on the learning rate gives some indication of a possible site of action. Because anticholinesterase agents such as prostigmine or edrophonium made the animals learn more quickly, we measured the cholinesterase level in the experimental, control and resting metathoracic ganglia: the results are shown in Table 1.

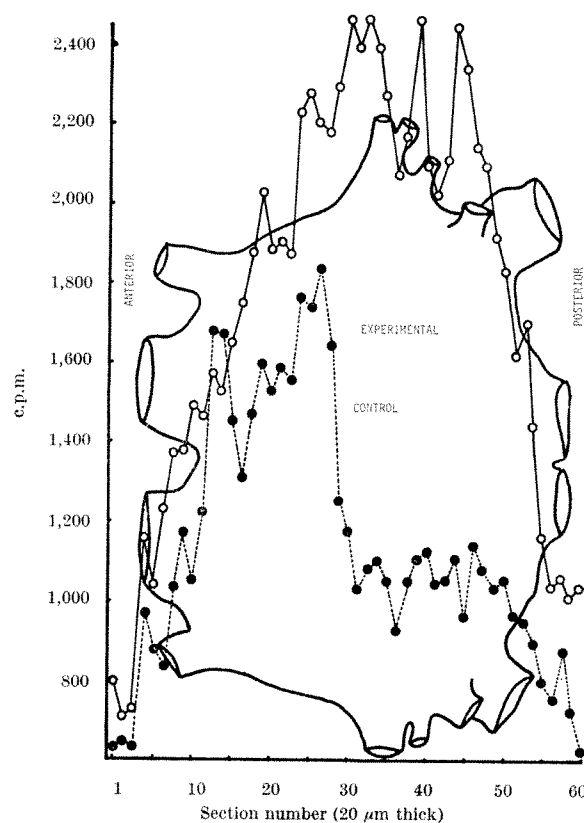

Fig. 1. Location of radioactivity in experimental control ganglia. The ganglion was embedded in wax and cut into sections 20 μ m thick. The activity in each section was counted. Experimental ganglia had the higher activity, more activity being present in the posterior end of the ganglion (to the right of the figure).

The metathoracic ganglia of the experimental animals had a much lower cholinesterase activity than the ganglia of the control or resting animals, the value being approximately one-third of that for the resting animal. This change in cholinesterase activity had taken place during the 30 min of the training process. A study of the rate at which the cholinesterase activity returned in the ganglia of the experimental animals showed that it took 3 days to return to the resting value. Simultaneous tests of the number of shocks required to bring another set of experimental animals back to the learning criteria during the three days after training showed that after three days the animal had effectively forgotten. Fig. 2 illustrates the recovery of the cholinesterase activity and the loss of memory of the animals. We have evidence indicating that the experimental ganglia produce less γ -aminobutyric acid (GABA) from glutamate than do the control or resting ganglia. Acetylcholine is probably the excitatory transmitter at the cockroach central nervous synapse and GABA is probably the inhibitory transmitter⁷.

Our results indicate that, among other changes, cholinesterase activity decreases markedly in the experimental ganglia on learning. This would facilitate synaptic transmission and could alter the synaptic ratio from an input: output ratio initially of, say, 20:1 to a value of 2:1 or even 1:1. The decrease in the level of GABA might also increase the likelihood of transmission, so that specific pathways would be facilitated. We interpret the difference between the experimental and control ganglia to mean that although both animals receive the same number of electrical shocks, there are some neurones in the experimental animals that receive a patterned sensory

Table 1. CHOLINESTERASE LEVELS

Metathoracic ganglion	μ moles acetic acid released/h/100 μ g protein
Experimental	1.22 ± 0.08 ($n = 21$)
Control	2.43 ± 0.19 ($n = 21$)
Resting	3.42 ± 0.53 ($n = 21$)

Fig. 2. Change in cholinesterase activity in the ganglion and the retention of learning. On training at day 0 the cholinesterase level in the experimental ganglion diminished rapidly, slowly returning to the normal level after 3 days (●—●). The experimental animals slowly forgot their training (▲—▲) during the 3 days and required an increasing number of shocks to reach learning criterion.

input simultaneously with the shocks; these neurones will receive greater stimulation and so effect a greater change in the level of cholinesterase and production of GABA involving specific pathways. Our demonstration of a greater turnover of RNA, enhanced protein synthesis, a rapid decrease in cholinesterase activity and a slower production of GABA in experimental animals leads us to suggest that the latter two changes constitute the basis of short term memory storage (1–3 days). Moreover, the changes in protein synthesis may bring about morphological changes that would be responsible for longer term memory.

Destruction of Lymphoid Cells by Activated Human Lymphocytes

THE mitotic activation of lymphocytes *in vitro* by histocompatibility antigens has some surprising features. Human lymphocytes are activated by isoantigens on fresh or X-irradiated lymphocytes of another donor (the mixed lymphocyte reaction), but not by isoantigens on human fibroblasts and HeLa cells, or on leucocytes killed in various ways, or on leucocyte fragments^{1–3}. The mixed lymphocyte reaction has been shown, in rats, to be immunological in nature. It is specifically abolished when tolerance is produced by neonatal injection of bone marrow cells bearing the isoantigens^{4,5} and is a primary response; yet approximately 2 per cent of the cells in the circulating lymphocyte population, in the rat, are directly responsive to lymphocytes bearing isoantigens associated with any one of a series of alleles present at the major histocompatibility locus⁵. Human lymphocytes are activated by X-irradiated cells from various human

* Test = culture (1 ml.) containing 2 × 10⁶ blood lymphocytes from an adult human donor in 20 per cent pooled human serum-gelatin in Eagle's MEM.

† Control = culture (1 ml.) matched to contain the same number of red cells and the same stimulant but lacking blood lymphocytes.

EB2 cells were labelled by incubation with Na⁵¹CrO₄ (1 μCi per 10⁶ cells) for 24 h and washed. The percentage release of ⁵¹Cr was determined after a 6 h period of incubation at 37° C with ⁵¹Cr-labelled EB2 cells. Maximum release on freezing and thawing = 80 per cent. ³H-Thymidine incorporation was determined after 24 h incubation with 0.5 μCi of ³H-thymidine as previously described¹; d.p.m. = disintegrations per minute. EB2 is a Burkitt lymphoma cell line. X-irrad. = X-irradiated with 6,000 r. All results are means of triplicates.

lymphoid cell lines (LCL) in a reaction closely similar to a unidirectional mixed lymphocyte reaction, but of considerably greater intensity^{1,2,6,7}. Cord blood lymphocytes, as well as lymphocytes of the adult, are responsive and a high proportion of the blood lymphocyte population is sensitive to antigens on the LCL cells. These experiments demonstrate the inbuilt reactivity of lymphocytes to certain antigens and the importance of "presenting" the antigens in the right way to the lymphocytes. Some cells seem to "present" their surface antigens in a way which "triggers" lymphocytes whereas others do not, a fact of practical importance in attempts to demonstrate tumour antigens by mixed cell tests.

The thymic-derived lymphocytes activated in the mixed lymphocyte reaction are thought to be effector cells with cytotoxic properties⁸. In human or pig mixed lymphocyte reactions, however, there is little indication of inter-destruction in survival tests based on dye-exclusion. Human lymphocytes stimulated with allogeneic lymphocytes in culture have been shown to be cytotoxic to Chang cells (human liver)⁹, but human lymphocytes were not damaged when exposed to a hundred-fold excess of allogeneic lymphocytes for up to 72 h (ref. 10). We have been able to demonstrate, using a chromium-release technique⁸, that human lymphocytes incubated for several days with irradiated LCL cells show a markedly enhanced capacity for the destruction of these cells (Tables 1 and 2). The cytotoxic effect seemed to require direct cell to cell contact; it was not obtained with supernatants of mixed cultures of irradiated LCL cells and blood lymphocytes.

Fig. 1. Amount of ⁵¹Cr released into the supernatant as a function of the number of ⁵¹Cr-labelled EB2 cells added. Human cord blood lymphocytes (2 × 10⁶ in 1 ml.) were incubated for 3 days with or without X-irradiated EB2 cells. 0.5 ml. of medium was removed and 0.5 ml. fresh medium containing the ⁵¹Cr-labelled EB2 cells added. After a further 18 h incubation the supernatants were separated from the cells and counted for ⁵¹Cr. ▲, Cord blood lymphocytes incubated with X-irradiated EB2 cells (10⁵); ●, cord blood lymphocytes without stimulant; ■, red blood cell controls. Points are means of triplicate cultures.

Fig. 2. Cytotoxic effect of adult human lymphocytes stimulated with X-irradiated EB2 cells. Adult human lymphocytes (10^6 in 1 ml.) were cultured with or without X-irradiated EB2 cells. The stimulation was measured by the addition of ^3H -thymidine 24 h before harvesting at the time shown (\times - - \times). The results are expressed as increments ("stimulated" minus controls) and are means of triplicate cultures. To measure cytotoxicity, 0.5 ml. of medium was removed from the cultures without disturbing the cells and 10^6 non-irradiated ^{51}Cr -labelled EB2 cells were added in 0.5 ml. medium. After incubation for 6 h the cultures were centrifuged and the supernatants carefully pipetted off. The cell button was dissolved in 0.1 ml. 1 M NaOH. The cytotoxic effect was measured by the percentage of ^{51}Cr released into the supernatant and the points are means of triplicate cultures. A batch of EB2 cells freshly labelled with ^{51}Cr was used at each time. Δ — Δ , Human lymphocytes incubated with X-irradiated EB2 cells (2×10^5); \bullet — \bullet , human lymphocytes without stimulant; \times — \times , red blood cell controls. Maximum release was measured after two cycles of freezing and thawing of the ^{51}Cr -labelled EB2 cells and is shown for each batch \square .

Nor was there any indication of the need for an antibody or other factor present in human serum, for positive results were obtained when all the cultures contained foetal calf instead of human serum. The cytotoxic effect on the target cells was a rapid process nearing completion in a few hours and apparently beginning as soon as cell contact was established. Killing of the target cells seemed not to result in death of the lymphocytes—that is, it was probably not a suicidal act. These results parallel reports of the effects of immune rat lymphocytes on mouse fibroblasts¹¹ and of immune mouse lymphocytes on a mouse mastocytoma¹².

The reaction was of first order with respect to target cells (Fig. 1), which recalls the first order lytic reaction of

Table 2. EFFECT OF ACTIVATED LYMPHOCYTES ON VARIOUS TARGET CELLS

CB=human cord blood lymphocytes. Other details as for Table 1.

mouse fibroblasts reported by Berke *et al.*¹⁵. Enhanced cytotoxic activity of blood lymphocytes of an adult was first apparent one day after incubation with X-irradiated LCL cells and was maximal at about 6 days (Fig. 2). The increase in cytotoxic activity roughly paralleled the rise in DNA synthetic activity but in other respects there was no correlation between the two activities (see Table 1). The induced cytotoxicity was not specific for a particular LCL, at least as far as EB2, EB4 and Jiyoye LCL were concerned, or even for human cells (Table 2). Mouse lymphoma (L5178Y) cells were lysed as effectively as EB cells by lymphocytes prestimulated with X-irradiated EB cells, even though X-irradiated mouse lymphoma cells are not able to induce significant mitotic activation of human lymphocytes in culture. Human lymphocytes mitotically activated with phytohaemagglutinin or staphylococcal filtrate¹³ did not show enhancement of cytotoxicity by contrast with results obtained with Chang cells as target cells⁹. Unstimulated peripheral lymphocytes from most adult and cord bloods were cytotoxic in some degree for LCL cells but there were quantitative individual variations in primary cytotoxic capability. Lymphocytes from human thymus (obtained at operation through the kindness of Dr B. Bradley) were activated in terms of DNA synthesis by incubation with X-irradiated EB cells but did not acquire cytotoxic competence (Table 3). Thymocytes have also been reported to show poor phytohaemagglutinin-induced cytotoxicity towards Chang cells¹⁴. The effector property may depend on the state of maturation of the thymus lymphocyte or may indicate that more than one cell type cooperates in the effector stage.

Table 3. LACK OF CYTOTOXIC ACTIVITY BY HUMAN THYMUS CELLS

Stimulant added to culture	Percentage ^{51}Cr release		^3H -Thymidine incorporation (d.p.m.)			
	Day 4		Day 3		Day 5	
	Test	Control	Test	Control	Test	Control
None	30	34	754	—	765	—
PHA (2 μg Burroughs Wellcome X5)	30	(34)	1,487	—	4,779	—
Staphylococcal filtrate (0.1 ml.)	26	(34)	470	—	693	—
X-Irrad. EB2 (10^5)	30	(34)	3,384	2,296	17,774	1,366

Human thymus cells (10×10^6 in 1 ml.) were cultured for the times shown, with or without stimulant. The cells were harvested at the time shown. $0.5 \mu\text{Ci}$ ^3H -thymidine was added 24 h previously. To measure the cytotoxic effect, 10^5 ^{51}Cr -labelled non-irradiated EB2 cells were added 24 h before harvesting. Other details as for Table 1.

Most reports of cytotoxic effects of lymphocytes on tumour cells and other cells assume that the cytotoxic reactivity is specifically directed towards the target cells. This is far from proven (see review¹⁴). Human lymphocytes activated by a variety of substances, including phytohaemagglutinin and bacterial products, have been shown to acquire enhanced capacity to kill Chang cells⁹. The cytotoxic specificity of splenic cells from mice immunized with allogeneic tumour cells, on the other hand, seems to be related to the nature of the transplantation antigens on the tumours¹². The conclusions from our own experiments are (a) that cytotoxic activation of lymphocytes is distinct from mitotic activation: both types of activation may occur after exposure to lymphocytes to antigen; (b) the specificity of the effector reaction against target cells is broader and different from that of the mitotic activation. It may also depend on the relative susceptibility of the different cell types to lethal damage.

The whole process of recognition and destruction of cultured LCL cells seems to be an example of a complete reaction of cellular immunity *in vitro* mediated by a single cell type. That this process may be an *in vitro* counterpart of an immunological surveillance mechanism is indicated by recent experiments (ref. 16 and unpublished data) in which similar results were obtained with lymphocytes and LCL cells originating from the same donor.

Migration of Small Lymphocytes from the Skin to the Regional Lymph Nodes

THE route of sensitization of lymphocytes to homografts has for long been a matter for speculation, and two schools of thought exist. It has been suggested that sensitization occurs either peripherally in the graft¹ or, alternatively, centrally in the regional lymph node^{2,3}.

In the case of the renal homograft, Strober and Gowan have clearly demonstrated that lymphocytes entering the allogeneic kidney are sensitized in the graft and leave again through the venous blood⁴. These cells then settle in lymph nodes and splenic white pulp where they transform into pyroninophilic cells which are so characteristic of the homograft and other cell mediated immunological reactions^{5,6}. Thus, in this particular instance, the evidence for peripheral sensitization is very strong. In the case of the skin homograft the route of sensitization is very much more difficult to demonstrate by direct methods. The chief drawback is the small size of the blood vessels to the graft bed, making them impossible to cannulate. Thus indirect evidence has been sought. Barker and Billingham have clearly demonstrated the importance of the lymphatics of the graft bed⁷. Grafts deprived of the lymphatic drainage enjoy considerably prolonged life, and furthermore do not sensitize the host. Similarly, tissue grafts placed in the hamster cheek pouch, which has no lymphatic drainage, also survive for a long time⁸.

It may be argued, however, that the importance of the afferent lymphatics lies in the fact that they afford a route by means of which antigenic material from the graft may reach the node and so effect a central sensitization. In favour of this alternative to peripheral sensitization, it has been demonstrated that the afferent lymph draining a skin homograft does not contain increased numbers of lymphocytes but does contain appreciable amounts of cellular debris⁹. Barker and Billingham have indicated, however, that if any antigenic cell debris does leave the graft it is not sufficient to sensitize the host⁷.

Furthermore, they showed that in the lymphatic-free skin graft preparation lymph containing lymphocytes did accumulate within the graft.

Any consideration of the route of sensitization must take into account the cellular changes in the lymph node draining a graft. The pyroninophilic reaction that is seen in these nodes is restricted to the diffuse cortical zone (=traffic area), and does not generally involve the germinal centres or medulla until late in the reaction^{6,10}. One route for central sensitization has been advanced which takes this cellular reaction pattern into account. Burwell suggested that the antigen enters the node via the afferent lymphatics and passes from the marginal sinus into the cortex through the post-capillary venules and submarginal capillaries^{2,3}. It is in these vessels that the lymphocytes entering the node in the blood are sensitized. If, however, a "classical" antigen is injected subcutaneously, then this is found to be localized in the medullary sinus cells and germinal centres, and not in the cortical blood vessels or diffuse cortex¹¹. Such classical antigens result in a clearcut plasma cell reaction in the medulla and antibody production¹².

It would considerably strengthen the case for peripheral sensitization if it could be shown that lymphocytes entering the skin (from the blood) can pass down the lymphatics and so reach the lymph node. The experiments described here were designed to test this point, and further to determine where in the node such lymphocytes settle. Do they reach the medulla as particulate material does, or do they show a preference for the diffuse cortical tissue where the homograft reaction occurs?

Peripheral blood lymphocytes were separated from heparinized rat blood (30 IU heparin/ml.) which had been collected by cardiac puncture. The lymphocytes were then concentrated to give a concentration of $20-30 \times 10^6$ /ml. in TC 199 and incubated with ³H-adenosine (10 μ Ci/ml.) for 45 min¹³. The lymphocytes were then washed once with TC 199, and concentrated so that 5×10^6 viable cells were present in 0.1 ml. of TC 199. This procedure labelled approximately 45-50 per cent of the small lymphocytes. Some red blood cells were also present in the inoculum and they acted as a convenient marker for the injection site. 0.1 ml. of the cell suspension was then injected intradermally into the lateral thoracic region of adult male isogenic rats; a clamp was placed over the needle track to prevent leakage of cells out until the needle hole had been sealed with 'Norbecutane'. Animals were killed at varying times up to 48 h, their draining and contralateral axillary nodes, the inguinal nodes and spleen were removed, fixed with Carnoy's fluid or formal saline and 5 micron sections subjected to autoradiography using Ilford L4 nuclear research emulsion. After 14-19 days' exposure at -20°C . the autoradiographs were developed and stained with either methyl-green-pyronin or haematoxylin/eosin.

At least three sections taken from different levels of each node and the spleen were entirely scanned using a $\times 100$ oil immersion objective. The numbers of cells seen in the marginal sinus, lymphoid follicles, diffuse cortical tissue and the medulla of the node were noted. Sections made through the skin in the area of the injection were also treated in the same way. As a control experiment lymphocytes were labelled and then killed by heating at 56°C for 20 min. After this treatment an average of 98 per cent of the cells were dead and yet still intact and labelled.

The results obtained were very consistent in each of the three animals killed at each time interval. Examination of lymph node sections from serially killed rats showed that during the 15 h following injection no labelled cells had reached any of the draining lymph nodes. In the sections of the injection site most labelled cells were seen amongst the injected red cell mass with very few labelled cells in the dermis. From the sixth hour onwards, however, labelled cells left the injection site and were seen in increasing numbers throughout the dermis. At the

Fig. 1. ^3H labelled lymphocytes in the marginal sinus of regional lymph node 21 h after injection (haematoxylin and eosin, $\times 800$).

injection site there was a vigorous polymorph infiltration and a few histocytes were also present.

In the draining nodes a few labelled cells were first found in the animals killed at 15 h. These cells were only seen in the marginal sinuses and occasionally in the cortical area immediately adjacent to that sinus. By 20 h, however, the number of labelled cells in the draining node had increased considerably and they were distributed through all zones of the node except in the lymphoid follicles and germinal centres when they were present. The majority of cells were, however, found in the diffuse cortical tissue (61 per cent) but significant numbers were also seen in the marginal sinus (30 per cent) and the cords of the medulla (9 per cent). By 24 h the progressive movement of the labelled cells across the node had continued and many more cells were seen in the diffuse cortex (88 per cent) with a few still in the marginal sinus (3 per cent), but little change in the number of cells in the medulla (9 per cent) some of which were now, however, in the medullary sinuses (see Figs. 1, 2 and 3).

In both 20 and 24 h regional lymph nodes, labelled lymphocytes were seen in the cortex near to, and in, the intermediary sinuses, and some labelled cells were seen in these sinus walls. Other labelled cells were seen in the proximity of post capillary venules, although no labelled cells were found in the lumen of these vessels. The distribution of the labelled cells was not uniformly spread throughout the diffuse cortical tissue, but had a segmental distribution. This segmental distribution also occurs if the cells are injected intravenously¹³ and may account for the segmental pattern of reaction in nodes—draining a homograft². Some radioactivity had been injected with the cells, and this gave rise to a light labelling in some of the macrophages of the marginal sinus and medulla (Fig. 3). This light degree of macrophage labelling was also seen in nodes examined 6 h after injection of the cells into the skin. A second possibility is that the light labelling may have been caused by label released from dead lymphocytes after their ingestion and destruction by the macrophages. This is, however, less likely.

By 48 h very few labelled cells were seen in the draining node in two out of the three animals, although in the third animal a significant number of labelled lymphocytes was found. The localization of these cells in the node was still, however, chiefly in the diffuse cortex (76 per cent) and medullary cords and sinuses (24 per cent). No cells were found in the marginal sinus. In another group of animals the labelled cells were injected into the tail. In these rats labelled cells were seen at 48 h in all instances in the draining inguinal nodes only with essentially the same distribution in the diffuse cortex (89 per cent) and medulla (11 per cent). A small number of the labelled cells which were seen in the cortex of these 48 h draining nodes

possessed a nucleolus and had cytoplasm with increased pyroninophilia. These cells could be considered to be activated lymphocytes, although the activating stimulus is not known.

Labelled cells were seen in very small numbers in the contralateral lymph nodes from 20 h onwards in most rats. The topographical localization of these cells was identical to those in the draining nodes. No labelled lymphocytes could be found in the more distant inguinal nodes or spleen.

In six control rats injected with labelled dead lymphocytes, there was a prominent histocyte reaction at the injection site by 24 h. Very few intact labelled cells were seen and these were all present in the needle tract and none had penetrated the dermis. No labelled cells were found in the draining, contralateral or distant nodes or in the spleen in these animals. Light labelling of lymph node macrophages was seen in this series also.

Summarizing these results, it may be said that lymphocytes introduced into skin gain access to the draining lymph node and localize in the diffuse cortical area or "traffic area". This is precisely the area in which the pyroninophilic reaction is found in response to a homograft. These cells must have reached the draining node through the afferent lymphatic vessels. They enter the marginal sinuses and can either pass down the intermediary sinuses and then migrate out of these sinuses into the diffuse cortical tissue, or else cross the walls of the marginal sinus and enter the cortex directly. Here they can remain for at least 24 h. This is an active process which requires viable cells. A number of the cells eventually enter the medullary sinuses and probably leave the node in the efferent lymph. The labelled cells cannot have reached the node through the blood stream for two reasons. First, the localization of the labelled cells in the lymph nodes was strictly regional and confined to the draining node; it is difficult to see how this could occur if the labelled cells had returned to the blood after injection into the skin. Second, it has been shown that intravenously injected labelled lymphocytes are found in all nodes and also the spleen and are rarely found in the marginal sinus or in the area of cortex immediately under it¹³.

Thus these experiments have demonstrated a second route of lymphocyte circulation from connective tissue through the lymphatics to the lymph nodes. Lymphocytes are ubiquitous in the connective tissues of the body, and can be shown to be leaving the skin continuously through afferent lymphatic vessels². Unless it is to be postulated that lymphocytes are produced in the connective tissue of the skin, for which there is no good evidence, then these cells must enter the tissue from the blood. As in the case of the blood→lymph node→lymph→blood recirculation¹³, the area of the node in which the migratory

Fig. 2. ^3H labelled lymphocytes in diffuse cortical tissue 21 h after injection (haematoxylin and eosin, $\times 560$).

Fig. 3. ^3H labelled lymphocyte in medullary sinus (\leftarrow) and lightly labelled sinus macrophages (\circ) in regional node 24 h after injection (haematoxylin and eosin, $\times 800$).

lymphocytes accumulate is the diffuse cortical zone. Such a connective tissue-to-node route was suggested by Sjövall in 1936¹⁴, but was discounted by Yoffey and Drinker as a major recirculation route because of the low number of lymphocytes present in peripheral lymph¹⁵. It is submitted, however, that although this route is not the major route of lymphocyte circulation it does become of paramount importance in the context of the homograft reaction. Using the data of Hall⁹ it may be calculated that lymphocytes (and other cells) reach the node through an afferent lymphatic at a rate of up to 3×10^6 per hour which could lead to considerable accumulation of cells in the node over a period of a few days.

Previous *in vitro* studies by me¹⁶ and others¹⁷ have shown that lymphocytes can be sensitized to foreign transplantation antigen by contact with homologous cells. Moreover, studies of the mixed leucocyte reaction have shown clearly that the result of this sensitization is the production of a population of pyroninophilic cells capable of mitosis which are very similar in their ultra-structure to many of the pyroninophilic cells found in the lymph node draining a homograft. The observations reported here taken together with these *in vitro* studies, and the demonstration of the importance of the lymphatics in sensitization to skin graft, make a very strong case for peripheral sensitization in the case of the skin graft, as well as the renal homograft.

Postsynaptic Action of Cobra Toxin at the Myoneural Junction

RECENT investigations of peptide fractions from cobra venoms suggest that the most potent acute toxicity arises from a curare-like block of the action of acetylcholine at the skeletal myoneural junction¹⁻³. I wish to report the effects on myoneural transmission of toxin T_3 from *Naja naja siamensis*—(Kaouthia) (Thailand cobra) venom, a pure peptide of known amino-acid composition⁴.

I used standard intracellular recording techniques at room temperature (18° – 22° C) on superficial fibres of the isolated frog (*Rana pipiens*) sartorius myoneural junction preparation⁵, with special attention to favourable signal-to-noise ratios. The nerve was stimulated at a frequency of 0.5/s at 5–10 min intervals. I used digital computers (Control Data 160-A and 160-G) for data collection, measurement, and statistical analysis. The Ringer solution contained 113 mM NaCl, 2.5 mM KCl, 4 mM MgCl_2 , 5 mM Tris (pH 7.3), 0.4 mM Ca^{2+} , and 4 mM Mg^{2+} . The concentration of toxin was 1.6×10^{-6} M.

With these divalent cation concentrations, end plate potentials (EPPs) consist of several summed miniature EPPs, and EPP amplitudes have a Poisson distribution⁶. I determined m , the average number of miniature EPPs comprising the EPP, in three ways from the measurements of EPPs and of miniature EPPs⁷.

Fig. 1 shows that after the addition of toxin, the EPP decreased and eventually attained an exponential rate

Fig. 1. Action of a pure peptide from cobra venom on myoneural transmission in the frog. At cross-hatching Ringer solution was replaced by solution containing toxin. \circ , \bullet and \square . Measurements on a series of 128 EPPs. \square , Measurements on spontaneously occurring miniature EPPs. A, Average EPP amplitude \pm s.e. EPPs without error flags at later times were too small, relative to the recording noise, for accurate measurements on individual responses. B, Quantal content $m \pm$ s.e. \circ , m , computed from the number of failures; \bullet , m , computed from the coefficient of variation of the EPP amplitude distribution; \square , m , computed by dividing EPP by miniature EPP amplitudes. C, Miniature EPP amplitude: \square , measured directly; \circ , computed as EPP/m ; \bullet , computed as EPP/m . The vertical line at the lower left gives approximate error limits for computed miniature EPPs.

Fig. 2. Waveforms of 128 averaged EPPs, before (smooth, heavy trace) and 150 min after (light, noisy trace) treatment with cobra toxin as described in the text. Waveforms have been amplified to match peak amplitudes; actual amplitudes were 2.1 mV before, 25 μ V after. Amplifier was capacitance-coupled with a time constant of 100 ms.

of decline. This time course indicates that the toxin acted irreversibly in these experimental conditions; washing with Ringer (not shown) halted the decline but caused only slight recovery after several hours. The lines *A* and *C* are parallel on semilogarithmic coordinates, indicating that EPP amplitude decreases because miniature EPP amplitude decreases; *m* remains unaffected. I have also found that the toxin blocks the response to micro-ionophoretic applications of acetylcholine and of carbachol (see also ref. 1). Thus, the toxin decreases the postsynaptic sensitivity to acetylcholine.

Fig. 2 compares the time course of averaged EPPs before and after application of the toxin. The waveforms superimpose: therefore, the toxin does not affect conduction in the nerve terminal, passive electrical properties of the muscle membrane, or the acetylcholinesterase. The toxin altered neither the spontaneous miniature EPP frequency nor the muscle fibre resting potential.

Some experiments showed a decline in *m* in addition to the decrease in miniature EPP amplitude. In these anomalous cases, the toxin usually increased the coefficient of variation of miniature EPP amplitudes while it decreased the average miniature EPP amplitude. This leads to a broader EPP amplitude distribution, therefore to a lower m_2 . Also, the broader miniature EPP distribution probably allowed the smallest miniature EPPs to escape detection, thus increasing the average miniature EPP amplitude and decreasing m_1 . In similar fashion, EPPs consisting of only one small miniature EPP probably were recorded as failures, thus decreasing m_0 . The broader miniature EPP distribution could arise from local variations in the accessibility of postsynaptic membrane to toxin molecules, because of variations in the connective tissue, Schwann cells and basement membrane covering the end-plate⁸. Also, some branches of the end-plate may lie on the surface of the muscle while others lie in the cleft between adjacent fibres⁹. Such mechanisms are likely because the time to reach an exponential decline, and the normalized rate of decline, varied by a factor of 3 even when two end-plates a few hundred μ m apart were monitored simultaneously.

Toxin *T_3* therefore acts specifically with low reversibility on the acetylcholine receptor at the skeletal myoneural junction. Homologous peptides occur in other elapid and hydropheid venoms; I have obtained similar but less extensive results with *Naja nigricollis* toxin α , the sequence of which is known¹⁰. It is still not known whether these toxins bind as specifically as they act.

I thank Mr D. Eaker for toxin and Mr F. A. Dodge, Mr A. Mauro, and Mr F. Ratliff for advice. Intracellular Responses to Light from Cat Pigment Epithelium: Origin of the Electroretinogram c-Wave

NOELL¹ first showed that the c-wave of the vertebrate electroretinogram (ERG) probably originates in the pigment epithelium because the c-wave disappeared in the rabbit after selective poisoning of the pigment epithelium by sodium iodate. Brown and Wiesel showed that the c-wave of the cat's local ERG attained maximum amplitude when the electrode was immediately adjacent to the pigment epithelium². They also obtained more direct evidence during brief intracellular recordings from pigment epithelial cells, which revealed larger potentials of similar time course but opposite polarity to the c-wave³. We have now obtained stable intracellular recordings which permit the slow light-evoked responses of pigment epithelial cells to be described in detail and identified positively as the origin of the c-wave.

The preparation and maintenance of the cat, and methods of stimulating and recording from the retina of the intact eye, have been described elsewhere^{3,4}. All responses were recorded from the area centralis after dark-adapting the retina at least 45 min. Recordings were made by glass micropipettes filled with 3 M KCl and a reference electrode on the temporalis muscle. The frequency response of the recording system was flat from 0–2,500 Hz.

The pigment epithelium was located by advancing the microelectrode to the retinal depth where the c-wave of the local ERG attained maximum amplitude. A slight additional advance penetrated a mechanical barrier, accompanied by a negative baseline shift of at least 20 mV and a marked diminution of the entire local ERG². Intracellular responses were sometimes recorded while passing through the barrier, but were more often obtained by penetrating the barrier and then withdrawing in 1 μ m steps until the baseline showed a negative shift of 50–60 mV. When such a resting membrane potential was recorded a characteristic slow negative response to light always appeared (Fig. 1).

Brown and Tasaki have shown by electrode marking that after penetrating the described barrier the electrode is located against the choroidal side of Bruch's membrane, while withdrawal through the barrier to the site of maximum c-wave amplitude places the electrode against the retinal side of the pigment epithelium⁵. Our intracellular recordings could only have been obtained from pigment epithelial cells, for they are the only cells between the two surfaces of this mechanical barrier. Numerous attempts were made to identify the recording site by

Fig. 1. Comparison of the local ERG and an intracellular response from a pigment epithelial cell. The intracellular response was recorded first; then the microelectrode tip was withdrawn into the photoreceptor layer and the ERG was recorded to an identical flash. The records on the right were photographed at a faster sweep to illustrate the similar time courses of the *b*-wave of the local ERG (bottom) and the early peak of the intracellular response (top). The responses were obtained in a dark-adapted retina with a 440 nm filter, stimulus intensity of 2.0 log *td* scotopic, stimulus spot diameter of 2.0 mm, and a repetition rate of one per 5 s. Negative responses are displayed downward, in this and subsequent figures, in accord with the conventions for both intracellular recording and ERG work.

electrophoresis through the microelectrode of Procion Yellow M4RS and Niagara Sky Blue 6B during intracellular recording. Although this technique succeeded readily with horizontal cells⁶, dye marks deposited in pigment epithelial cells during the same experiments were never recovered. Because these cells are specialized for exchanging substances between the retina and choroid⁷, the dye may have been lost into the choroidal circulation; also it may have diffused into adjacent pigment epithelial cells through tight junctions^{8,9}.

Intracellular responses obtained in thirty-three impalements were maintained stably from 3–40 min. Fig. 1 shows an intracellular response compared with the extracellular response (local ERG) elicited by an identical flash after withdrawing the microelectrode tip back into the photoreceptor layer. The intracellular response was always negative (hyperpolarizing) and in the best recordings reached a maximum amplitude of 20 mV superimposed upon a resting potential of 60 mV. The slowness of this response is its most distinctive feature, distinguishing it from all other potentials evoked by light from the normal mammalian retina. The time constant of the rise averaged 800 ms (775–850), while the time constant of the fall was nearly the same, about 750 ms. The identity of the slow intracellular response with the *c*-wave is indicated by their similar time courses, including rise, peak, and fall times. The slow intracellular response was always opposite in polarity from the *c*-wave, and larger than the *c*-wave, as expected if the *c*-wave is generated across the apical membrane of the pigment epithelium.

The identity of the intracellular slow potential and the *c*-wave is strongly supported by their similar response to

changes in stimulus parameters. Fig. 2 shows effects of stimulus duration upon both the intracellular slow potential and the *c*-wave. At short stimulus durations the intracellular response peaks after termination of the stimulus. As stimulus duration increases, response amplitude increases until a plateau is reached which is only prolonged by still longer stimuli. Similar effects occur in the *c*-wave of the local ERG, which for any given stimulus duration follows closely the time course of the intracellular response. When stimulus intensity was increased, the amplitude of the intracellular slow potential increased and the response peak occurred at progressively longer delays after termination of the stimulus. Here also, corresponding effects occurred in the *c*-wave recorded after withdrawing the microelectrode into the photoreceptor layer.

Intracellular responses also exhibited an early negative peak on the rising phase of the slow potential. The records at a faster sweep speed, on the right side of Fig. 1, show that this peak has the same latency and time course as the *b*-wave of the local ERG. Because these two responses have the same polarity, and the *b*-wave is known to be generated more proximally in the retina², we concluded that the intracellular negative peak is not generated across the apical membrane of the pigment epithelium, but represents intracellular detection of an extracellular potential, as found in glial cells¹⁰.

Spectral sensitivity functions for the intracellular slow potential under dark-adapted conditions are shown in Fig. 3. The curves obtained closely resemble rod sensitivity functions of cat S-potentials. No Purkinje shift occurred when the criterion voltage for plotting spectral sensitivity was raised from 2.5 to 5.0 or 7.5 mV, although flashes were sufficiently intense to excite cones, particularly at the long wavelengths. In addition, there was no Purkinje shift after light-adapting the retina by intense flashes, and recovery of the response after light adaptation was very slow. In short, a cone contribution was sought but not found, although the recordings were in the area centralis where the cone population is densest and where most S-potentials are influenced by cones as well as rods^{4,11}. It seems, therefore, that the intracellular slow potential depends upon absorption of light by rhodopsin. This result also agrees well with studies of the *c*-wave, which is absent in pure cone retinas^{12–14} (with one apparent exception¹⁵), disappears in light-adapted mixed retinas¹⁶, and follows a rod spectral sensitivity function^{17,18}. Although rhodopsin has been identified in pigment epithelial cells¹⁹, two observations indicate that light which triggers the *c*-wave is absorbed in the rod outer segments. The *c*-wave has been reported absent from isolated pigment epithelium-choroid preparations of cold-blooded eyes²⁰, but the pigment epithelium may be damaged in such cases. Recently a more critical result was obtained by Liebman *et al.*¹⁹, who showed that the action spectrum of the *c*-wave is not modified by pre-absorption in rod rhodopsin in the

Fig. 2. Comparison of the local ERG and the intracellular response of a pigment epithelial cell as a function of stimulus duration. Intracellular responses were recorded first; then the microelectrode tip was withdrawn into the photoreceptor layer and local ERGs were elicited by identical stimuli. The responses were obtained in a dark-adapted retina with "white" stimulus flashes (colour temperature 2,850 K) at an intensity of 1.7 log *td* scotopic. The stimulus spot was 2.0 mm in diameter and the repetition rate was one per 5 s.

Fig. 3. Spectral sensitivity of the intracellular response of a pigment epithelial cell in a dark-adapted retina. Responses to increasing stimulus intensity were obtained at different wavelength maxima spaced from 440 to 660 nm. The stimulus was 2.0 mm in diameter, 480 ms in duration, and was repeated every 5 s. Responses were measured from baseline to peak. Spectral sensitivity curves were then derived by applying constant response criteria to the amplitude-intensity functions. The relative sensitivity values at the criteria were then converted to spectra of equal quantum intensities. Criterion voltage: ○, 2.5 mV; □, 5.0 mV; Δ, 7.5 mV. The solid line was drawn through data points for the 2.5 mV criterion of response amplitude. The spectral sensitivity of dark-adapted cat S-potentials is also shown for comparison (dotted line)⁴.

manner expected if the rhodopsin which initiates the *c*-wave were contained in the pigment epithelium.

The chief remaining problems concern how rod excitation initiates an electrical response across the apical membrane of the pigment epithelial cell, the functional significance of this response, and why it is not similarly initiated by cone excitation. Electrical interaction of excited rods with pigment epithelial cells seems unlikely, for tight junctions have not been found between these cells²¹⁻²³, and because the 10-20 nm extracellular space should effectively uncouple the membranes from electrical interaction²⁴. An important key seems to be the slowness of the response generated across the pigment epithelial membrane. The faster rise time of the rod component of cat S-potentials⁴ indicates that even if the output signal of the rod receptor acts as an intermediate in initiating the slow potential of the pigment cell, it could account for only a fraction of the slowness of that response. Diffusion across the extracellular space will also play only a small part unless the molecule is very large or the interstitial matrix acts as a diffusion barrier^{24,25}. It seems likely, therefore, that the ion or molecule that diffuses between the two cells and initiates the slow potential is generated slowly, as would be the case with a late photoproduct.

Fragmentation of a Geometrical Figure viewed under Intermittent Illumination

WHEN a simple target is viewed as a currently occurring retinal image which is confined to a specific locus, the target has been reported to lose contrast and to disappear¹⁻³. The restriction of an image to a specific retinal locus is commonly termed a "stabilized retinal image". This is the reverse situation to that encountered in normal vision where eye movements change the position of the retinal image several times a second. For more complex targets such as geometrical figures viewed as stabilized retinal images, intermittent disappearance and reappearance of the figure in whole or in part have been reported⁴⁻⁷. This striking phenomenon, usually outside the subject's previous visual experience, has been termed "fragmentation". The common methods of investigating fragmentation are voluntary steady fixation, viewing as a partially stabilized retinal image using a contact lens and as a prolonged after-image (a completely stabilized retinal event)⁴⁻⁷. These methods in order progressively impose restraint on the image with respect to its retinal locus. Another method of investigating fragmentation was described by Evans⁸ and McFarland⁹, who note reports of fragmentation by subjects viewing geometrical figures for brief time intervals. Typically, the stimulus is viewed tachistoscopically near the recognition threshold after which the subject records his observations. This sequence is then repeated for many trials. We wish to describe another method of producing and studying fragmentation, by viewing a geometrical figure under intermittent illumination.

Eight subjects viewed the geometrical figure shown in Fig. 1, in a range of frequencies of intermittent illumination. They were instructed steadily to fixate the centre of the figure and to make verbal and drawn reports of fragmentation, while the frequency of intermittent illumination was slowly increased from 1 to 30 c.p.s. and then

Fig. 1. Stimulus pattern used in this investigation.

Fig. 2. Typical patterns of fragmentation reported by subjects viewing Fig. 1, under intermittent illumination.

decreased again to 1 c.p.s. The frequency of intermittent illumination was held constant while subjects made their reports. Typically, a complete trial lasted 8 to 10 min. Intermittent illumination was produced by placing the outline figure shown in Fig. 1 before a General Radio Company 'Strobotac' type 1531-AB, operating with a Mazda FA/7/s flash tube (standard fitment). The spectral output of this source was continuous within the visual spectrum. Flash duration was rated at 3 μ s for frequencies from 2 c.p.s. to 11.5 c.p.s., and at 1.2 μ s for frequencies above 11.5 c.p.s., power rating at 0.35 W. The geometrical figure was drawn in black Indian ink on white translucent paper. To ensure an evenly illuminated stimulus, a sheet of white translucent plastic was placed between the geometrical figure and the strobatorch. The diameter of the circle subtended a visual angle of 3° and the line width of 7 min of arc, when viewed at optical infinity. A condition of optical infinity was produced by instructing subjects to wear their corrective lenses if normally worn for distance and to view the geometrical figure through a convex lens of focal length 50 cm. The plane of the stimulus was situated in the focal plane of the lens. Viewing was monocular, the non-viewing eye being occluded.

The only illumination present during the experiment was that provided by the strobatorch. All subjects were experienced observers and had prior knowledge of the phenomenon. To minimize any unpleasant effects which might have been induced by the intermittent illumination, the visual field was restricted to that immediately surrounding the geometrical figure. This was achieved by placing a circular aperture in the stimulus plane. At optical infinity the diameter of the aperture subtended a visual angle of 11½°. The stimulus was centrally placed with respect to the aperture.

All subjects reported fragmentation of the stimulus. Some typical observations are shown in Fig. 2. These observations are consistent with those reported when usual methods of producing retinal image stabilization were used. All subjects also reported distortion of the figure, a finding also consistent with previous reports¹⁰. Although there seem to be qualitative similarities of fragmentation between this method and those described previously, it remains to be seen whether there are also quantitative similarities. Strong qualitative and quantitative similarities have already been demonstrated for geometrical figures viewed by steady fixation, with a contact lens and as a prolonged after-image^{6,7,11,12}. Subjects' qualitative observations showed that generally fragmentation occurred between 2 and 16 c.p.s. But there were strong indications from subjects' reports that more fragmentation took place between 6 and 10 c.p.s. than at other frequencies.

This possibility was investigated. Four subjects who had previously reported fragmentation qualitatively reported the occurrence and duration of fragmentation by pressing a button. These responses were recorded on an Esterline-Angus events recorder. The stimulus conditions were those already outlined, except that subjects viewed the geometrical figure at six specific frequencies of intermittent illumination: 3, 6, 9, 12, 15 and 40 c.p.s. Subjects reported fragmentation for 3 min at each frequency. Frequencies were chosen to cover the range within which fragmentation had been reported to occur, qualitatively. A frequency of 40 c.p.s. was chosen because, being well above each subject's C.F.F. for central vision, it simulated a steady fixation viewing condition. The results are shown in Table 1.

Table 1. TOTAL DURATION OF FRAGMENTATION REPORTED BY FOUR SUBJECTS AT FREQUENCIES OF INTERMITTENT ILLUMINATION OF 3, 6, 9, 12, 15 AND 40 C.P.S.

Subject	3	6	9	12	15	40
1	75.0	109.0	154.75	60.0	53.25	16.50
2	3.75	13.5	16.25	17.50	7.0	3.75
3	1.75	84.25	167.50	8.75	1.25	0.00
4	24.75	128.50	171.0	86.0	44.50	45.25

Figures are given in seconds. Total viewing time at each frequency for each subject was 180 s.

Table 1 shows the total time for which each subject reported fragmentation occurring at each frequency of presentation. For three subjects the amount of fragmentation was frequency dependent, that is, it occurred maximally at 9 c.p.s., and took up progressively less of the viewing time at greater or smaller frequencies. One subject reported a similar amount of fragmentation at all frequencies of presentation.

In summary, it can be said that viewing a geometrical figure in conditions of intermittent illumination provides a new method of producing fragmentation. Because these preliminary findings indicate that the amount of fragmentation is dependent on the frequency of presentation, this method may provide a means of investigating temporal factors underlying the phenomenon.

I thank all those who acted as subjects in the study.

Mislocation of Test Flashes during Saccadic Image Displacements

If a stationary source of light is flashed briefly during or just before a saccadic eye movement, it is less easily detected than when the eye is stationary¹⁻³, and its location relative to a fixed background is misperceived^{4,5}. These phenomena have sometimes been taken to support the theory that an efferent signal from the oculomotor system actively modifies the visual input signal during a voluntary eye movement so as to 'cancel' the visual effects of the movement⁶, with a view to maintaining the stability of the perceived world. On this theory one would not expect to observe such perceptual anomalies if the eye were held stationary and the retinal image moved in saccadic fashion by external means.

I have reported recently^{7,8} that the threshold for perception of faint flashes can be elevated to about the same extent by passive as by active image displacement. A further series of experiments using the same apparatus have now confirmed that illusory displacement of a flash also occurs in relation to a saccadically displaced field in the absence of oculomotor activity. These experiments have made it possible to study the effects of the time interval between flash and image displacement, and of the speed of displacement, on the magnitude of the illusion.

A horizontal luminous scale subtending 11° was used as the moving field. Its image (white on a dark ground) was projected with a luminance of 1 log foot Lambert on a vertical screen 1 m from the observer in a dark room. It could be rapidly displaced horizontally up to 4° in either direction by means of a mirror mounted on an electroencephalogram (EEG) pen motor. The displacement, which was free of overshoot, could be set to occupy 8 ms or 40 ms, and took place at randomly varied intervals in the neighbourhood of 4 s, the return stroke coming 2 s later. A triangular arrow, which could be illuminated by an electronic flash tube, was arranged so that its image was deflected with the scale and always coincided objectively with the central scale division.

The timing of the flashes was varied randomly in a range of either 100 or 200 ms about the time of onset of the field displacement, and the subject was asked to report the position on the scale that the flash appeared to occupy. To eliminate cues from a stationary fixation point, the subject was instructed to fixate the central scale division in its initial position. Any reflex response to scale movement would have a latency of the order of 100 ms, and so could be discounted⁹.

Typical results are shown in Fig. 1, in which perceived flash location is plotted against the time between flash and onset of field displacement. It is clear that mislocation is confined chiefly to flashes presented in the 50 ms or so before and during displacement, the error curve rising to a maximum at time of onset. Field displacements to left and right produce illusory shifts of similar magnitude in opposite directions.

The effect of increasing the time of displacement from 8 ms to 40 ms is shown in Fig. 2. At the slower speed both the magnitude and time range of illusory displacement were considerably diminished. The position of the peak was not affected, although the "overshoot" error in the opposite sense reached its maximum later—that is at the end of the displacement. Not all subjects experienced this "overshoot".

An interesting anomaly was reported spontaneously by some observers. The flash (which was practically instantaneous) sometimes appeared to have two locations in succession, as if onset and offset happened at different times. Where this ambiguity arose, the subject was asked to report the "earlier" perceived location. Successive "ghost" images in response to transient stimulation are not uncommon¹³, and are perhaps attributable to the oscillatory impulse-response of the visual system¹⁴. The same explanation may account for the "paradoxical double localization" occasionally found by Bischof and Kramer⁵ for flashes presented during saccadic eye movements.

Localization errors when a test line was briefly illuminated against a moving background have been reported briefly by Sperling and Speelman¹⁰, who gave no figures,

Fig. 1. Perceived location of flash on scale as a function of time interval between flash and onset of displacement. Actual location was fixed at 4. Displacement took 8 ms. Measured displacement to L was slightly larger (2.8 divisions) than to R (2.4 divisions). (○) Left; (+) right.

Fig. 2. Effects of duration of image motion on perceived location. (●) 8 ms (500°/s); (○) 40 ms (100°/s).

but stated that "localization during eye movement usually can be predicted from localization during object movement". Taken together with my results (especially Fig. 2), this suggests that some correlation might be expected between the magnitude of the illusory displacement observed with saccadic eye movements and the speed of these movements. In any event, although my results do not conclusively exonerate the oculomotor system, they show that it need not be implicated in order to account for mislocations during saccadic movement. I have argued elsewhere that visual stability during eye movements does not require a "cancellation" mechanism¹¹.

How then are such mislocations to be explained? The clue seems to be the finding (confirmed in a further series of experiments on fifteen subjects with the assistance of Mr K. Bradshaw) that the most significant errors are confined to the period before and during displacement of the image. The inference seems to be that the location of a flashed image relative to its background involves an interaction between the neural signals generated by each, which interaction takes an appreciable time to complete. If during this time the retinal image of the background shifts to a new position, the integrative process will have two different "background" signals to cope with, each making its own contribution to the total weight of evidence with respect to flash location. The later the flash comes, before the moment of transition, the greater will be the weight attached to the new scale-position as compared with the old. Thus the greater will be the illusory displacement of the flash, which is then objectively at the centre of the old scale-position. When the flash is delayed until after the scale-displacement, it is objectively at the centre of the new scale-position, so that only the residue of the earlier background signal remains to contribute any bias to the computation of relative flash location. This bias would account for the "overshoot" observed with some subjects.

If this explanation is valid, the shape of the error curves in Figs. 1 and 2 should be closely related to the time course of the postulated interaction. The data suggest a duration of the order of 50 ms for the integrative process, which is comparable with that inferred for the flash-detection process in the earlier experiments^{7,8}. Retinal ganglion cell discharges of about this duration are typical in response to brief threshold stimuli¹². The correspondence is at least encouraging; and the strong dependence of the magnitude of the illusion on the duration of the movement strengthens the hypothesis that it depends essentially on the degree of overlap in time between the neural events representing the flash and those representing the scale in its successive positions.

I thank Miss M. A. Steele, Dr D. P. Andrews, Mr P. G. H. Clarke and Mr K. Bradshaw for assistance, and the Medical and Science Research Councils for financial support.

Test of Gregory's Constancy Scaling Explanation of the Müller-Lyer Illusion

MUCH of the recent interest in geometrical illusions has centred on a size constancy explanation by Gregory¹⁻³. Size constancy occurs when the apparent size of an object remains constant, independent of the distance of the object from the observer, even though the size of the retinal image varies with the distance. The mechanism which produces size constancy has been called constancy scaling².

In Gregory's theory—a modification of perspective theory⁴—geometrical illusion figures are considered to be similar to two-dimensional projections of three-dimensional figures. As in three dimensions, constancy scaling operates to increase the apparent size of apparently more distant parts of a figure, and to decrease the apparent size of apparently nearer parts. In a two-dimensional figure, perspective features provide the observer with cues for judging the apparent distance of parts of the figure. These perspective features trigger constancy scaling, which affects the apparent size of parts of the figure and produces an illusion, even though the figure need not be seen as having depth.

Gregory's theory cannot account for all illusions because, as Day⁵ has pointed out, illusions can be generated by figures without perspective features, such as the dumbbell version of the Müller-Lyer figures. It is still, however, of interest whether illusions in figures containing perspective features can be explained by the operation of constancy scaling. The Müller-Lyer figures seem to have perspective features: the wings and their directions. If Gregory's theory is correct, constancy scaling should thus influence the perception of the Müller-Lyer figures.

Gregory² assumes that Müller-Lyer figures are similar to projections of typical three-dimensional objects. For example, Fig. 1a—with the wings directed outwards—is similar to a projection of the corner of a room, where the central axis corresponds to the corner and the outside wings correspond to the intersections of the walls with

Fig. 1. a and b, Müller-Lyer figures. c and d, The same figures with enlarged width of central axis.

Fig. 2. Mean judged length of the central axes of Müller-Lyer figures as a function of the absolute length and the direction of the wings (●, inward; ○, outward).

the ceiling and with the floor. Because of the effect of the wings as perspective cues, the central axis is judged as though it were farther away than the wings, that is, as though the figure were a three-dimensional object. Accordingly, constancy scaling operates, and increases the apparent length of the central axis. On the other hand, Fig. 1b—with the wings directed inwards—has the perspective cues of a projection of an outside corner of a building. The central axis is thus judged as though closer than the wings and therefore appears too small because of constancy scaling.

If Gregory's theory is correct and internally consistent, constancy scaling not only augments the apparent length of the central axis of Fig. 1a but also should augment its apparent width. That is, if constancy scaling is involved, both the apparent length and the apparent width of the central axis should be affected and should be distorted in the same direction.

The present study provides a direct test of the assumption of constancy scaling by determining whether subjects' length and width judgments of Müller-Lyer figures are distorted in the same direction. Because the Müller-Lyer figures usually consist of relatively fine lines, as shown in Figs. 1a and 1b, any illusion in the perception of the width of the central axis might not be noticed on casual observation. With thicker central axes, however, as shown in Figs. 1c and 1d, any illusion in the judged widths should be readily discernible. Note that these figures provide the same perspective depth cues as do the standard Müller-Lyer figures: the wings and their directions.

In the figures used here, the inward and outward wings met the central axis at 30 and 150 degrees, respectively. Four sizes of the central axis were used: 40 × 109, 27 × 136, 64 × 170 and 43 × 212 mm. Figures were presented one at a time, vertically as in Fig. 1, at a distance of 105 cm from the subjects and about 12 cm above eye level. The figures were projected on to a green blackboard with a slide projector.

Subjects were told to judge the apparent length and width of the central axis of each figure. The response sheet contained a horizontal and a vertical line which met and ended at a point near the upper left corner of the sheet. The subject responded by making a mark on each line to indicate the length and width of the central axis. The figure remained present while the subject made his response. No more than two subjects were tested at a time. Fourteen subjects judged each of the eight figures six times in randomized blocks of trials. Responses were measured to the nearest millimetre.

The results of the experiment contradict Gregory's theory. Fig. 2 shows that the Müller-Lyer illusion occurred:

Fig. 3. Mean judged width of the central axes of Müller-Lyer figures as a function of the absolute width and the direction of the wings (●, inward; ○, outward).

the lengths of the central axes with outward-directed wings were judged longer than the corresponding axes with inward-directed wings. As explained above, it follows from the theory that the width judgments should have been distorted in the same direction; but they were not. Fig. 3 shows that the width judgments were, rather, distorted in the opposite direction: the widths of the central axes with outward-directed wings were judged smaller than the corresponding axes with inward-directed wings. A repeated-measures analysis of variance revealed that this average difference (1.13 mm) was significant ($P < 0.01$).

One of the most popular explanations of the perceptual distortion of the lengths of these figures has been Gregory's perspective theory. But this theory does not predict the judgments of width obtained here. This study was a critical test, for the figures used have substantial cues for depth and should, according to the theory, have triggered constancy scaling. Given its inability to account for the perceived width of the figures, Gregory's theory cannot provide a consistent account of the Müller-Lyer illusion.

Facets of Control in Human Walking

Using eight normal barefoot male subjects, we have studied, for both feet simultaneously, the timing characteristics of the various phases of heel and toe contact with the ground. Two types of experiment were performed for walking on the level, one with speed fixed at 4.5 feet/s while pace frequencies were varied between 1.25 and 4.00 per s; another with speeds of natural walking ranging from 2.0 to 6.7 feet/s. We chose to experiment with barefoot subjects to eliminate the possible influence of different footwear, recognizing that walking characteristics, with and without footwear, would not necessarily be identical. For both natural and forced pace walking

we found that averages of the various footswitch phases, when normalized with respect to the average periodic time, remained fairly constant. Also, for natural walking, both pace frequency and step size seem to depend on the square root of the speed.

The barefoot subjects had shaped, fine mesh stainless steel electrodes taped over the heel and toe regions of both feet on top of an insulating layer of adhesive tape. The toe electrode covered the area under the big toe as well as the pad of the foot directly behind the toes, and the heel electrode covered the load bearing parts as indicated by the thick-skinned regions. They kept pace with a motorized cart whose speed could be controlled, and after traversing some 20 feet over which a steady-state walk could be reached the subjects walked on a roughened sheet of 1/16 inch aluminium 30 feet long and 18 inches wide.

A small junction box on a belt around the subject's waist held four resistors with values in the proportions 8 : 4 : 2 : 1 and commoned at one end. The other ends of each resistor were connected to their respective footswitch electrodes and the common junction was connected to a 6 V battery and a resistor in series mounted on the cart. The aluminium walkway was connected to the latter resistor by way of the shield of a signal cable running from the cart. The footswitch states determined the voltage appearing across the resistor. This voltage was led through the signal cable directly to our digital computer which was programmed to sample it at the rate of 200 Hz while the subject was over the aluminium surface. Then the programme translated the signal into graphic responses associated with each footswitch and effected analyses of the data acquired for the number of steps taken over the 30 foot length. Average values of the various phases of walking were computed, together with their mean deviations, variances and standard deviations. With the onset of the right-heel-down phase as the starting condition, two average down phases of each footswitch performance were plotted. Results were derived from the averages of three to twelve sampled steps depending upon speed of walking or frequency of pacing. The maximum mean deviation recorded was 0.078 and the maximum standard deviation 0.084 for a time period of around 0.5 s. In general, values for these deviations were considerably less. Various plots were made from the computed data.

Fig. 1 is typical and shows average periodic time as measured for the onset of the right heel down state plotted on the abscissa, with ordinates each expressed as a fraction of the average periodic time as follows: RHD, the time for which the right heel is down; RTD, the time

Fig. 1. Timing normalized to right period of footswitch phases against right period.

Table 1. PHYSICAL DATA OF SUBJECTS AND AVERAGES OF FOOTSWITCH PHASES FOR SPEED 4.5 FEET/S

Subject	Weight pounds	Height Feet Inches	RSTA	RSW	RTD	RHD	DWB
FH	175	5 10	0.59	0.41	0.51	0.34	0.1

RVB	158	5 10	0.58	0.42	0.55	0.30	0.08
AOQ	133	5 8	—	—	—	—	—

Each of the factors RSTA, RSW, RTD, RHD and DWB is expressed as proportions of the time from right heel contact to right heel contact. RSTA is the right stance phase; RSW the right swing phase; RTD right toe down; RHD right heel down; DWB double weight bearing, being the phase for which both the left and right extremities are simultaneously in contact with the ground.

Table 2. VALUES OF THE CONSTANTS k AND n , FROM THE RELATION $f = kv^n$ OF PACE FREQUENCY f AND SPEED v , DERIVED BY PLOTTING RESULTS FOR EACH SUBJECT ON LOG-LOG PAPER

Subject	k	n
FH	0.44	0.49
MM	0.39	0.56
CM	0.43	0.50
EPE	0.43	0.50
FM	0.36	0.63
RL	—	—
RVB	0.46	0.50
AOQ	0.44	0.50

for which the right toe is down; RSTA, the right stance phase; RSW, the right swing phase, DWB, double weight bearing—the time for which both the left and right extremities are simultaneously in contact with the ground. In most cases variations about and with respect to the mean values of each of these factors were less than 10 per cent. Table 1 shows physical data relevant to the subjects and the averages of the various factors. The similarities between these factors for the various subjects, and their relative constancy, independent of the periodic time, and hence pace length, are noteworthy. Typical of the responses of all the subjects tested, Fig. 2 depicts the variation of the same factors as discussed in connexion with Fig. 1 but with varying speeds. At the top of Fig. 2 is a plot of the variation of period with speed. The factors RHD and DWB seem to produce the most significant percentage changes over the range of speeds. In all cases declines in RSTA, RTD, RHD and DWB with speed, and an increase in RSW, were found.

Fig. 2. Timing normalized to right period of footswitch phases for various speeds.

Fig. 3. Step size and step frequency against speed. ●, Fitted curve, $y = 2.28\sqrt{x}$; ○, step size; ▽, frequency.

The observation of the symmetrical properties associated with the left leg factors was interesting, though not unexpected. All the factors remain within a few per cent of their right leg counterparts.

Fig. 3 shows a plot of pace frequency f and the step size s derived from the relation $s = v/f$, against speed v . Also plotted is a curve whose equation is $y = 2.28\sqrt{x}$ and which seems to fit the step size data well. Plotting the results of the several subjects on log-log paper and assuming the relationship $f = kv^n$, where k and n are constants, their values turn out as in Table 2. It thus seems to a good approximation that pace frequency is dependent on the square root of speed and, as a consequence of the relation $s = v/f$, so is the step size. This shows an interesting aspect related to the control of walking speed: both pace frequency and step size increase with the square root of speed, and therefore pace frequency and step size are linearly connected. Control over the range of speeds examined is thus effected by the concomitant adjustment of these two parameters. Assuming, for the moment, that pace length alone decides speed, it is evident from geometric considerations for stiff-legged walking¹ that greater speeds will necessitate greater excursions in the centre of gravity of the body, thus calling for more lift energy per step. It would seem that the human locomotion system is so arranged as to cause increases in frequency of the pace in such a way as to compensate for increasing lift energy demands.

Giraffid Horns

HENSHAW¹ has accepted Coope's premise² that giraffes have retained the skin-covered horn-like structures of the palaeomerycids, from which they are descended, because there have been no significant changes in the climate—the hypothesis being that the formation of antlers is a response to environmental temperatures. But the nature of the

giraffe horn can be seen in relation to the form of the animal and its social requirements, without any reference to the cervid antler³. As Henshaw states, the horn-like structures of the giraffe are analogous to the summer antlers of deer, in that they have points of resemblance, but there is no justification for invoking climate as an explanation of their form. They are specialized structures in the giraffe *Giraffa camelopardalis* L. of which the skin covering is no more velvet-like than that covering the rest of the animal's body, and it is certainly not vascular like the velvet skin of antler buds.

It is more pertinent to argue the case of the okapi *Okapia johnstoni* Selater in which the horns are primitive structures which have remained unchanged since the Miocene. But they have probably not developed further because elaborate structures would be a hindrance in the forest environment, and because the social behaviour of this solitary animal did not warrant the development of more than it already possessed.

The cervid antler must be shed and regrown from time to time because bone is brittle compared with horn and often becomes broken. An adult male giraffe, weighing some 1,500 kg, would require a massive palmate antler to withstand the weight of the body behind it if used in fighting. This, in its turn, would require much greater neck muscles, the volume increasing by the cube, and the whole weight of the giraffe would alter out of all proportion to the advantage gained, necessitating pillar-like legs to support it. We would, in fact, be left with a giant *Libythere*, an animal which has already evolved and faded out of the evolutionary picture.

Directional Water-shedding Properties of Feathers

FEATHERS repel water strongly because they are porous. Their porosity can cause a large air-water interface, relative to solid-water interface, to form under a drop resting on the system of interlocked barbs (the vane). In this way the apparent contact angle (θ_A) increases to values far greater than any (θ) known for plane surfaces^{1,2}.

While investigating those structural properties of feathers which are responsible for their water repellency, I have found that drops of water on feathers tend to roll off distally. This is a clear adaptation to shedding water; a tendency for drops to roll proximally might cause wetting of the skin. The directional movement of water was studied by measuring the angle of tilt required to roll drops of water of known volume off the outer surface of freshly plucked breast feathers of several species, in eight directions of movement of the drop relative to the lie of the barbs (Fig. 1). Angles required for movement towards the base of the vane (directions B, D, X) were considerably greater than for movement towards the apex. A correlation was found between the tilt angle and the angle of movement of the drop relative to the distal barbules (Fig. 2). These project distally roughly parallel to the rachis, and overlies the proximal barbules and, to a varying extent, the barbs. To produce drop movement by tilting in the same directions on the ventral surface of the feathers, larger drop volumes were required. Here, tilt angles correlated with the angle made by the passage

of the drop relative to the lie of the barbs (Fig. 3); again, less tilting was required to roll drops distally than to roll them proximally, but tilt angles were greater than on the dorsal surface. In a particular direction of movement, both on the dorsal and ventral surfaces, tilt angle varied with drop volume (Fig. 4). A maximum drop volume was reached beyond which the same degree of tilting was required to cause rolling. Below a certain volume, the drop would not move. Tilting facilitates movement of the drop by increasing its gravitational potential energy, which acts against the tendency of the solid to attract the liquid. The variation of tilt angle with drop volume reflects this effect. A drop on a surface to which water is continuously added will reach a maximum height related to contact angle; if further water is added, the drop spreads³. Increasing drop volume on a feather beyond this point causes local spreading of the drop edge so that it makes new contact with asperities in the surface, which impede movement.

For a drop front to climb up and over a ridge, energy is required, and apparent advancing contact angles result which are larger than that on the flat surface: this is the so-called "edge effect"^{4,5}. It is interesting that directional water repellency similar to that on the vane was found on the non-coherent edge to the vane of breast feathers of *Alca torda*. Here, the barbules are filamentous and the distals project towards the tip of the feather at an angle of about 45° to the plane of the feather. Drops of water studied by a microprojector on this surface made contact with these barbules in different ways, according to whether the specimen was tilted downwards towards the tip or the base of the feather. In the former case, the advancing front of the drop overlaid the distals. In the latter case, the distals rose up at the drop edge to meet it; the mechanism for directional water repellency here

Fig. 1. Coherent vane of breast feather, showing barbs and distal barbules. Directions studied: tilting to A, distally, parallel to rachis; B, proximally, parallel to rachis; C, distally, parallel to barbs; D, proximally, parallel to barbs; E, distally, at 90° to barbs; F, proximally, at 90° to barbs; G, distally, at 90° to rachis; H, at 90° to rachis, towards rachis.

Fig. 2. Outer surface of breast feathers of \circ , *Larus marinus*; \circ , *Cygnus columbianus*; \bullet , *Anser canalicus*; \times , *Aythya australis*. Each point is mean of ten. Standard errors varied from 0.50 to 3.17 degrees of tilt. Drop volume 10 μ l. Tilt angles measured to nearest 5°.

is probably related to the ease of passage of the drop distally, by virtue of this effect, and the rising up of the distal barbules when the feather is tilted down basally impeded the travel of the drop. A similar effect was observed on breast feathers of *Podiceps cristatus* (museum skin). For the drop to move basally, the "ridges" are greater, and more gravitational potential energy is required for movement. That this explanation may also be applied to the vane of breast feathers is indicated by the finding that in *Phasianus colchicus*, where the distal barbules are relatively short and do not overlie the barbs (unlike the other species studied), little directional water repellency was found (Fig. 5).

It is thus likely that directional repellency is conferred in this way: as a drop moves distally off the feather, it presses down the distal barbules in its path. As it moves proximally, the barbules rise up against it. This mechanism must be considerably enhanced by the great degree of longitudinal curvature of breast feathers of water birds (work in progress). On the ventral surface, the barbs are presumably the operative ridges and their structure must be such that it is easier for a drop front to pass distally than proximally, that is, the solid angle⁴ in cross-section must be larger on the edge of the barb towards the feather tip than on the opposite edge. In the case of *Aythya australis*, microscopic examination of the inner surface of the feather shows that the tips of the proximal barbules lie along the barbs and project towards their tips. These barbule tips are raised above the plane of the barbs in ventral view and must therefore contact the water drop: for this reason it is possible that an effect similar to that described for the distal barbules occurs

Fig. 3. Ventral surface of breast feathers of *Aythya australis*. Each point is mean of ten. Standard errors varied from 1.25 to 2.47. Drop volume 10 µl (○), 20 µl (●). Tilt angles measured to nearest 5°.

Fig. 4. Inner surface of breast feathers of *Aythya australis*; drop movement in direction A. Each point is mean of ten. Standard errors indicated. Tilt angles measured to nearest 5°.

Fig. 5. Outer surface of breast feathers of *Phasianus colchicus* (○) and *Corvus monedula* (●). Drop volume 10 µl. Each point is mean of ten. Standard errors varied from 0.50 to 4.40. Tilt angles measured to nearest 5°.

here also. It should be noted that movement of water drops in this way requires a large receding contact angle, and configuration of asperities such that no water is left behind⁴. Further work on this feature of feathers is in progress.

DDE thins Eggshells of Captive American Kestrels

EGGSHELL thinning in several species of raptorial and fish-eating birds, whose populations and/or reproductive success have declined dramatically in recent years, has been correlated with residues of DDE [1,1-dichloro-2,2-bis (p-chlorophenyl) ethylene] in their eggs¹⁻³. DDE, a common metabolite of DDT [1,1-trichloro-2,2-bis(p-chlorophenyl) ethane] and a nearly universal contaminant in the food of these birds, has been considered to be the major chemical responsible for eggshell thinning.

Heath, Spann and Kreitzer induced significant eggshell thinning and cracking in penned mallards (*Anas platyrhynchos*) by feeding the birds low dietary levels of DDE⁴. To determine if this chemical would also cause thinning of the eggshells of the American kestrel (*Falco sparverius*), we placed twelve pairs of hawks on a diet containing 10 p.p.m. p,p'-DDE on a dry weight basis (2.8 p.p.m. on a wet weight basis), beginning on March 30, 1968. This dosage was equivalent to residue levels commonly found in food items of raptors in the field⁵⁻⁸. The DDE (99 per cent pure) was dissolved in cottonseed oil and added to a diet of ground meat. The hawks were continued on the dosage until the experiment ended in 1969. No insecticide was added to the diet of ten pairs of non-dosed hawks. Clean oil had been added to their food since March 11, 1966, in amounts equal to that added to the diet of the dosed group. Both groups of hawks, dosed and non-dosed, were similar in age, but had somewhat different histories.

In 1968 and 1969, we collected the first egg laid by all pairs in both groups, where possible, for determination of shell thickness and pesticide content. Methods for handling shells and contents of the eggs are given elsewhere⁹.

Table 1. DDE RESIDUES AND SHELL THICKNESS OF KESTREL EGGS

Diet and year	Eggs analysed for residues	Av. residues (p.p.m. wet weight) \pm s.e.*	Range	Shells measured	Average thickness (mm) \pm s.e.	Range	Percentage thickness decline (1969)
Non-dosed							
1968	10	0.62 \pm 0.05	0.37-0.80	10	0.188 \pm 0.007	0.130-0.210	
1969	10	0.71 \pm 0.05	0.38-0.96	10	0.184 \pm 0.008	0.130-0.210	2.1
DDE dosed							
1968†	10	3.09 \pm 0.45	1.05-5.89	8	0.186 \pm 0.005	0.165-0.203	
1969	9	32.4 \pm 2.78	17.4-44.2	8	0.168 \pm 0.004	0.153-0.185	9.7‡

* Lipid weights averaged 6.5 per cent of the fresh weight of egg contents.

† In two cases where females laid their first egg before initiation of dosage, residues from a later egg in their first clutch were reported.

‡ Significant decline ($P < 0.001$), paired t -test. Only eggs from females that laid both years were compared.

In 1968, the hawks in the dosed group laid their eggs from one day before dosage began (two pairs), to seven weeks after dosage began; in 1969 these hawks had been on dosage approximately one year when they laid their eggs.

Eggs were analysed for chlorinated hydrocarbons by the WARF Institute. Samples of the entire egg contents were oven dried at 40° C for 24-36 h, ground with sodium sulphate and extracted with a mixture of ethyl ether and petroleum ether (70 : 170) for 8 h in a Soxhlet. Clean-up and preliminary separation were by two elutions through a florisil column (5 per cent ethyl ether in petroleum ether and 15 per cent ethyl ether in petroleum ether). Analysis was by electron capture gas chromatography (Barber Coleman Pesticide Analyser model 5360, Sr 90). The first elution was analysed on a 5 per cent DC 200 on Cromport XXX at column temperature 195° C; the second and check samples of the first were analysed on a 5 per cent QF-1 on Cromport XXX at column temperature 180° C. Injector temperatures were 230° C; detector temperatures were 240° C; nitrogen flow rates were 70-90 ml. per min. Columns were glass, 4 feet \times 4 mm. Polychlorinated biphenyls (PCB) were identified by peak matching and confirmed by dehydrochlorination with KOH, but were not quantified.

Average shell thickness of eggs laid by our hawks in 1968 is compared in Table 1 with thickness of eggs laid by the same females in 1969. Average shell thickness of eggs laid by DDE-dosed hawks in 1969 was 10 per cent less than in 1968 ($P < 0.001$); the 2 per cent decrease in average shell thickness of eggs laid by non-dosed hawks in 1969 was not statistically significant.

Earlier, we induced eggshell thinning in kestrels by feeding them a diet containing DDT in combination with dieldrin (composed of 95 per cent HEOD which is 1,2,3,4,10,10-hexachloro-6,7-epoxy-1,4,4a,5,6,7,8,8a-octahydro-1,4-endo,exo-5,8-dimethanonaphthalene)⁹. Because DDT metabolizes to DDE, the DDE stored in the birds' tissues probably contributed to the thinning of these eggshells. Dieldrin has been shown to cause eggshell thinning in mallard ducks¹⁰, but not in pheasants (*Phasianus colchicus*)¹¹. Its contribution to eggshell thinning in combination with DDT and/or its metabolites is not known.

The DDE residues found in the eggs are reported in Table 1. All are based on the fresh weight of the egg contents. The eggs from the non-dosed group contained an average of less than 1 p.p.m. DDE during both years; those of the dosed group contained an average of 3 p.p.m. DDE in 1968 and an average of more than 30 p.p.m. in 1969. Average residues of DDT plus DDD [1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane] did not exceed 0.28 p.p.m. in any experimental group during either year. No group contained an average of more than 0.06 p.p.m. dieldrin. PCB occurred in comparably small amounts.

Judging from the levels of DDE found in our kestrel eggs in 1969, the amounts of DDE reported from twenty-seven British peregrine falcon (*Falco peregrinus*) eggs (av. 15.7 p.p.m.; range 2.6-30.8 p.p.m.)¹² may have been large enough to have caused some of the eggshell thinning reported for that population¹³. High levels of DDE have also been reported in seven peregrine eggs from Northern Canada (range 10.4-41.8 p.p.m.)¹⁴; eggshell thinning in this population has not been documented.

DDE-induced thinning of kestrel eggshells in a controlled experiment further strengthens the hypothesis that this chemical is an important factor in eggshell thinning in wild raptorial and fish-eating birds.

We thank R. G. Heath for statistical consultation and the Forest Glen Annex of the Walter Reed Army Medical Center and the US National Institutes of Health for rodents used in the birds' diets.

Acid and Alkaline Phosphatase Activity in the Liver of Brown and Rainbow Trout

THE susceptibility of the rainbow trout to liver cell tumours following the administration of aflatoxin is well documented¹⁻³, as is the refractory behaviour of brown trout⁴. The different responses of these two closely related species probably indicate variations in basic metabolism. We decided to investigate histochemically some enzyme systems of the livers from brown and rainbow trout. Although histologically these livers were similar, the activity and distribution of the acid and alkaline phosphatases showed distinct variations. The activity of alkaline phosphatase was greater in the brown than in the rainbow trout (Fig. 1a and b), while acid phosphatase was more active in the rainbow than in the brown trout (Fig. 1c and d). The distribution of the phosphatases varies throughout the fish kingdom^{5,6}, and the significance of the present findings is uncertain. The metabolic differences in these two species may begin to explain the inverse response to the induction of liver cell tumours. A significant loss of alkaline phosphatase from the livers of ducklings fed aflatoxin has already been reported⁷, as has the elevation of various serum enzyme concentrations, including alkaline phosphate, in the pig⁸. We are extending histochemical studies on the effect of aflatoxin at various doses on the two species of trout, and

Fig. 1. a, Rainbow trout, alkaline phosphatase in liver; b, brown trout, alkaline phosphatase in liver; c, rainbow trout, acid phosphatase in liver; d, brown trout, acid phosphatase in liver.

hope to elucidate the different effects, if any, on the enzyme systems in the livers with special reference to the phosphatases.

Evidence for *Anopheles squamosus* Migration?

IN normal tropical and sub-tropical conditions most species of anopheline mosquitoes usually fly only short distances in search of food, shelter and breeding sites. Experimental investigations on *Anopheles funestus*¹, *A. gambiae*² and *A. melas*³ in Africa, *A. quadrimaculatus*⁴ in the United States of America, *A. argyritarsis*⁵ in Canada, *A. flavirostris*⁶ in the Philippines and *A. culicifacies*⁷ in India, have demonstrated that most adult mosquitoes

do not normally fly more than 3–5 km from a site of origin or release.

Although it is very difficult to prove that mosquitoes can disperse far afield, one African anopheline, *Anopheles pharoensis*, has been credited with performing migratory flights over considerable distances⁸. This species has been recorded on separate occasions as having apparently travelled over 29 km⁹, 56 km¹⁰ and perhaps as much as 280 km⁸ in the deserts of North Africa and the Middle East. Several such migrations have been correlated with the occurrence of a full moon⁸.

Another species, *Anopheles argenteolobatus*, belonging to the same subgenus and series as *A. pharoensis* (*Cellia*, *cellia*), has been reported to show remarkable fluctuations in density at the edge of its range in Southern Africa^{11,12}, with the possible interpretation that this species too may sometimes migrate to new territory. A further species, *A. squamosus*, similarly belongs to the same subgenus and series as *A. pharoensis*, the larvae being virtually indistinguishable. I report here that numbers of *A. squamosus* were recently collected at Amani in Tanzania under circumstances suggesting the arrival of an immigrant swarm.

Amani is a diffuse human settlement, situated at an altitude of about 1,000 m atop the heavily forested Eastern Usambara Mountains of north-eastern Tanzania. Since 1951, the East African Institute of Malaria and Vector-Borne Diseases has been located at Amani. Staff of the institute have carried out much malariological work in the district, including detailed mosquito surveys, with one result being that during the years from 1951 to 1967 *A. squamosus* was not recorded at Amani. The species is known to be relatively common, however, in some parts of the Usambara foothills, below the forested level, at altitudes around 200 m and distances of at least 10 km from the institute at Amani¹³.

For several years a mercury vapour lamp has been operated irregularly in the institute's grounds for collecting

insects. On the evening of December 23, 1968, the lamp was switched on at dusk (1830 h), after having not been used for some weeks previously. When visited at 2100 h a number of *Anopheles squamosus* females were observed among the insects attracted to the lamp. By 2200 h a total of thirty-one *A. squamosus* females were collected, but no more arrived thereafter. Twenty specimens were dissected later, of which fifteen were found to be unfed and with resting-stage ovaries, while five were fully gravid. Two of those with undeveloped ovaries were parous and the remaining thirteen nulliparous. All females contained sperms in the spermatheca. No malaria or filaria parasites were found.

Meteorological conditions at Amani were steady and typical for the season during the week leading up to December 23. A short rainy season had occurred throughout the region during November, with rainfall for the month totalling more than 15 inches at Amani. Rainfall on December 23 and for the previous five days was nil. On December 24 the maximum temperature was 27.3° C, the minimum temperature 16.1° C and the relative humidity was 60 at 1500 h and 86 at 0900 h. A new Moon had first appeared on the night of December 21, but on the 23rd there was complete cloud cover in the evening and slight mist.

* Collection at dawn.
† No collection.

On ensuing nights more *A. squamosus* were attracted to the lamp soon after dusk. The numbers collected each evening by 2200 h are shown in Table 1. Moderate catches, including three males, were made during the last week of December and a few more specimens were caught in the first half of January. Very few specimens arrived later than 2200 h and, although the lamp was always left on until after dawn, daily inspections at 0730 h yielded a total of only three additional *A. squamosus* females. The only other anophelines collected during the entire period were single females of *A. ziemanni* and *A. coustani*.

All possible anopheline breeding places within a mile of the lamp were searched on December 24, 27 and 30, 1968, January 2, 7 and thereafter at approximately weekly intervals until the end of March 1969. No *A. squamosus* larvae were discovered and there has been no other indication that the species managed to establish breeding in the area. The lamp failed to attract any more *A. squamosus* when used on numerous occasions during 1969 and on every night during December 1969 and January 1970.

In order to reach Amani by flying, *A. squamosus* adults would have needed to indulge in appetential behaviour¹⁴ of a migratory nature quite distinct from the usual short-range journeys in search of food, resting places and so forth. Even if passively wind-borne, in similar fashion to the migration of frit-flies and aphids¹⁵, the resulting dispersal of *A. squamosus* apparently contrasted with the

trivial flights regularly performed by mosquitoes in general and resembled the special migratory behaviour known to be a feature of *A. pharoensis*.

The failure to detect more *A. squamosus* at Amani during the 14 months following these observations supports the belief that this immigration was an unusual and isolated event. There is no way of determining the place of origin of the mosquitoes, except that it was probably at least 10 km away from Amani in the mountain foothills or beyond. Because the catch included some males it is feasible that the specimens collected might have bred locally. The sudden and transient incidence of *A. squamosus* at Amani can, however, only be accounted for by immigration of a population which did not survive.

In tropical situations direct evidence for the dispersive movements of wild mosquitoes is difficult to acquire. These observations on *A. squamosus* indicate that this species may resemble *A. pharoensis* and possibly *A. argenteolobatus* in performing flights of a migratory nature,

Age Dependency of Response in an Insect Chemoreceptor Sensillum

THE electrical responses of contact chemoreceptors on the mouthparts of many species of Diptera can determine whether or not a fluid medium is ingested. In the blowfly *Phormia terranova*, the responses of the large bristle-like sensilla, which occur in two aboral patches on the labellar lobes, regulate the extension of the proboscis and the opening of the labellar lobes. The responses of a single sensillum may mediate this action if stimulated with water or with certain sugars in aqueous solution¹. Without extension and opening, feeding is impossible. Rejection thresholds seem to be determined to some extent by the responses of the type 1 ("salt") receptor cell, one of the four types of chemoreceptor cell contained within each sensillum².

I summarize here some evidence of changes in sensitivity of two of the receptor cell types, 1 and 3 ("water"), which seem to be correlated with the age of the adult insect and which suggests that insect age may need to be considered in a full analysis of feeding behaviour in flies. The electrical responses of types 1 and 3 receptor cells which result from stimulation with water and various electrolyte solutions are now well known^{3,4,7,8} and represent preparations made from adult flies aged between 3 and 5 days from emergence from their puparia. Using flies maintained at 25° C in conditions of alternate periods of 12 h darkness and 12 h illumination (about 450 foot candles),

and provided with sucrose solution and raw meat as food, the electrical responses of cell types 1 and 3 were measured in flies of known ages up to 30 days, in all cases during the lighted phases of the illumination cycles. The stimulus solutions were water and NaCl (0.1, 0.2, 0.5 and 1.0 M). Ten flies were sampled on each successive day and the responses of four of the longest sensilla in each labellar preparation were recorded. (These sensilla may be defined from Wilczek's map⁸ as "largest, right 10, 11 and left 10, 11"; they are about 350 μ m in projecting length.) Each was stimulated four times with each of the test solutions, applied in a random sequence.

The responses are plotted as the mean adapted frequency of action potential generation against age for type 1 cells (Fig. 1a) and for type 3 cells (Fig. 1b). Any cells which failed to respond were ignored in calculating the mean discharge frequencies. In this connexion there was an increasing incidence of such cells among the samples of receptors, in which the ability to generate impulses had been altogether lost as the age of the flies increased. In Fig. 2, the incidence of type 1 cell failure (no response to 1.0 M NaCl) as a percentage of the forty cells in each daily sample has been plotted against age. It was rare to find an insect where response failure had affected some rather than all or none of the four cells examined. Between days 16 and 25, the mean incidence of type 1 cell failure in all the flies remains approximately constant near 60 per cent, but when flies were analysed individually only 27 per cent of the total sample of 100 insects between these age limits showed partial receptor failure (Fig. 3). This indicates

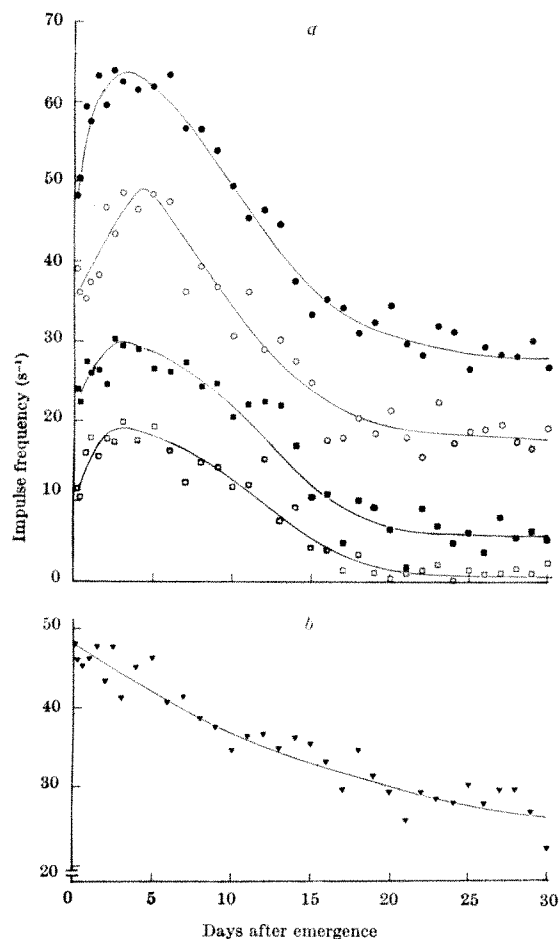

Fig. 1. *a*, Mean action potential discharge frequencies of type 1 receptor cells (after 350 ms of stimulation) as a function of insect age. Between days 4 and 30 (inclusive) each daily age sample was obtained over a period $\ll 8$ h. Stimulus solutions: \bullet , 1.0 M NaCl; \circ , 0.5 M NaCl; \blacksquare , 0.2 M NaCl; \square , 0.1 M NaCl. The responses of ten receptors represent the sample for each day, except on day 1 (30) and days 2 and 3 (20). *b*, As *a*, but for responses of the type 3 receptor cells stimulated with distilled water.

Fig. 2. The dependence of the percentage of inoperative chemoreceptor cells (type 1) (\blacksquare) upon the age of the insect. Sample sizes: day 1 (120 cells), days 2 and 3 (80 cells), all others (40 cells). The diagram also shows the mortality (\square) of flies in a parallel culture of 500 insects kept in the same conditions as those used in the experiments.

Fig. 3. Incidence of differing extent of chemoreceptor (type 1) failure per fly, in a sample of 100 flies of mixed ages between 16 and 25 days inclusive. Four cells in each fly were examined.

that there is some synchronization of failure in an individual fly. Occasionally, cells were found where the receptor potential could still be elicited, but where impulse generation was disabled.

In type 1 cells, the electrical responses are maximal when stimulated with NaCl solutions at about day 3. The response threshold rises with age after 3 days, but after day 20, the decline in sensitivity is more gradual. In type 3 cells, however, the discharge frequency diminishes steadily from the day of emergence of the fly. The rejection of a solution for ingestion can be brought about by stimulation of the type 1 cell, even in the presence of sucrose which, applied alone, elicits acceptance through stimulation of the type 2 "sugar" receptor, and therefore the consequence of a decline in sensitivity of the type 1 cell might be to allow acceptance of a wider range of solutions as food. If flies become less well able to forage for food as they age, it is conceivable that the survival value of an ability to ingest materials more often encountered, even if of less suitable content, may exceed that where only a more ideal food can elicit the ingestion response.

The type 1 cell discharge frequency increases with concentration of applied sodium chloride, whereas that of the type 3 cell decreases. Cohen has suggested⁶ that two such "opposing" receptors may be used to detect a stimulus intensity, here concentration, which elicits a combined minimum or zero output from both. In 3 day old flies, when the threshold of the type 1 receptor is at its lowest level, there is only a restricted concentration zone, between 60 M and 70 mM NaCl, which does not evoke a response from either type 1 or 3 cells. With increasing age, this silent zone widens; at 20 days it extends from

25 mM to 95 mM NaCl, and the properties for precise measurement of concentration of the opposing receptor system that are potentially present in younger insects are lost.

It is interesting that the mortality plot for these flies (superimposed on Fig. 2) shows a similar time-course to the plot of incidence of receptor cell failure. It is difficult to understand how a fly could feed at all if there were no peripheral chemosensory drive to initiate the reflex opening of the labellar lobes or the eversion of the proboscis. Perhaps massive chemoreceptor failure may be a factor of which the time of onset is important in determining the life span of the fly, especially because there is some evidence (Fig. 3) that such failure is approximately synchronized in any individual fly. Other sensilla on the tarsi of these flies may, however, initiate the proboscis extension reflex¹, and other chemoreceptor cells within the labellar chemoreceptors exist for which age dependent changes in response have not yet been investigated, notably the type 2 or "sugar" receptor, a cell of great importance in initiating the eversion and opening reflex.

Magnesium as a Toxic Element

THE soils over serpentine rocks are renowned for their barrenness, the causes of which vary enormously because the term "serpentine" embraces a wide variety of soil types. Sometimes, for a variety of reasons, these soils are very toxic to certain plants.

Hunter and Vergnano¹ observed toxicity symptoms in oat plants growing in a soil contaminated with serpentine. They reproduced these symptoms in culture by adding nickel to the media and correlated the symptoms with the content of nickel in the plants. Soane and Saunder² presented data which suggested that chromium, as well as nickel, toxicity might be important in some Rhodesian serpentine soils.

One Scottish serpentine soil, from near the hill known as Meikle Kilrannoch, in Glen Doll, Angus, is very toxic in greenhouse conditions. *Avena sativa* (oats variety 'Victory') and a non-serpentine race of *Agrostis stolonifera*, collected from Oxford, are very stunted when grown in this soil, with root growth almost completely inhibited. I have investigated the causes of this toxicity.

Soil for analysis (Table 1) was collected from the top 6 inches of the barest areas of the site, sieved (1 mm pores for chromium and nickel, otherwise 2 mm), and air dried. Normal ammonium acetate was used to extract the exchangeable cations, which were analysed by atomic absorption spectrophotometry. Phosphorus was extracted by Truog's reagent—0.002 N sulphuric acid plus 3 g/l. of ammonium sulphate; it was determined colorimetrically.

Table 1. ANALYSIS OF TWO SOILS FROM MEIKLE KILRANNOCH

	Exchangeable cations (mequiv./100 g)			Phosphorus soluble in dilute acid p.p.m.	Total Ni and Cr (p.p.m., semi-quantitative)		pH (1 : 2.5 soil-water suspension)
	Mg	Ca	K		Ni	Cr	
(a)	11.9	0.3	0.05	2	1,000	4,000	6.8
(b)	10.1	0.5	0.04	2	1,500	4,000	6.7

Nickel and chromium were analysed by X-ray fluorescence, and pH was determined in a 1 : 2.5 soil-water mixture. All the above ground parts of the oats grown in the Meikle Kilrannoch soil were used for analysis (Table 2) after digestion of dried samples in concentrated nitric acid. Calcium and magnesium were determined in an EEL atomic absorption spectrophotometer, potassium in an EEL flame photometer and nickel and chromium by X-ray fluorescence in a Philips Pw 1540 spectrograph. A reference analysis of healthy oats grown on a fertile soil is included in Table 2.

Table 2. METAL CONTENT OF OAT SHOOTS

	Ca	Mg	Ni	Cr
Meikle Kilrannoch soil	1,262	11,020	20	< 10
John Innes potting compost No. 2	4,735	2,330	< 5	< 10

Figures are p.p.m. of material oven dried at 105°C.

The soil had high contents of nickel and chromium, but they are unlikely to have been responsible for the toxicity. The symptoms shown by the plants grown on this soil were not those of heavy metal toxicity, and moreover there was comparatively little heavy metal in the plants. These plants contained much less nickel and chromium than those growing in another, non-toxic, serpentine soil³.

Tissue of *Agrostis canina* growing at Meikle Kilrannoch was analysed with a quartz glass Hilger spectrograph of the Littrow type for Ni, Cu, Mn, Co, Cr, Fe, Al, Mo, Zn, Pb, Ba and Ti, but none of these seemed likely to be present in quantities large enough to be toxic.

The possibility that magnesium ions were toxic was assessed in water culture experiments. The influence of magnesium ions on (a) a serpentine clone of *Agrostis canina* from Meikle Kilrannoch (clone MK/1) and (b) a non-serpentine clone of *A. stolonifera* from Oxford (clone PC/2) was investigated using single salt solutions of magnesium sulphate. Six concentrations of magnesium were used, and every treatment had eight replicate jam jars of about 330 ml. capacity, covered with aluminium foil, each containing two rootingtillers from each clone. The growth of the roots was measured first after 48 h in distilled water, after which the roots were transferred to the test solutions and measured after a further 48 h. Results are expressed as the ratio of root grown in test solution to root grown in distilled water (see Table 3). Ratios were satisfactorily distributed and not transformed before analysis.

Clearly magnesium ions can be surprisingly toxic in single salt solutions. (No difference was found between the toxicities of magnesium sulphate, chloride and nitrate³.) Moreover, the serpentine clone was tolerant of higher concentrations of magnesium than was the non-serpentine clone.

The difference in ability to grow in a magnesium solution is not fortuitously connected with the specific difference between *Agrostis stolonifera* and *A. canina*, for magnesium susceptible races of *A. canina* and tolerant races of *A. stolonifera* have been found at other sites³.

Magnesium toxicity in both soil and water culture can be ameliorated by the addition of calcium, and magnesium is toxic only when the concentration of calcium is sufficiently low. For example, 0.5 p.p.m. of Ca⁺⁺ added to a solution containing 10 p.p.m. of Mg is sufficient to cause a substantial, if not complete, amelioration of toxicity.

Table 3. MEAN RATIO OF LENGTH OF LONGEST ADVENTITIOUS ROOTS IN TEST SOLUTION TO LENGTH OF LONGEST ADVENTITIOUS ROOTS IN DISTILLED WATER OF CLONE PC/2 AND MK/1 ± STANDARD ERROR OF MEAN

Clone	Magnesium (p.p.m.)					
	0	0.5	1.0	2.5	5.0	10.0
MK/1	1.03 ± 0.069	0.94 ± 0.059	0.90 ± 0.084	1.14 ± 0.056	1.00 ± 0.084	0.97 ± 0.089
PC/2	0.82 ± 0.099	0.92 ± 0.056	0.75 ± 0.059	0.56 ± 0.043	0.27 ± 0.016	0.15 ± 0.027

Although the soil from Meikle Kilrannoch probably represents an extreme in toxicity, adverse effects of high concentrations of magnesium in the presence of low soil calcium are almost certainly of widespread importance on serpentines. Walker⁴ and Kruckeberg⁵ observed reduced growth of non-serpentine plants in some American serpentine soils. They hinted at possible toxic effects of magnesium, but concluded that calcium deficiency is the principal cause of the reduced growth in the serpentine soil. This interpretation has practical value because the deleterious effects on plant growth can be cured by the addition of calcium. But the emphasis on a calcium deficiency rather than a magnesium toxicity is unfortunate because (a) non-serpentine soils with comparably low contents of calcium do not affect plant growth in a manner similar to serpentine soils, and (b) plants can be actively poisoned by the toxic soils and do not show symptoms of deficiency. It seems that calcium is deficient only in the context of high concentrations of magnesium. Recent work on calcium⁶ has suggested that a major function of this element is to ameliorate the toxicities of other elements.

This work throws light on another interesting problem. A non-serpentine maritime race of *Armeria maritima* produced much healthier growth on the Meikle Kilrannoch soil than would have been expected from the results for oats and *Agrostis stolonifera*. Kruckeberg⁵ found that maritime species tolerated serpentine soils, but he had no explanation for this. In view of the high ratio of magnesium to calcium in seawater, perhaps maritime plants are to some extent preadapted to serpentine soils. Magnesium toxicity might be an important and hitherto under-considered factor in the maritime environment.

I thank Dr S. R. J. Woodell for help and criticism. This work was carried out while I was in receipt of a studentship from the Natural Environment Research Council.

Resonance Raman Scattering of Laser Radiation by Vibrational Modes of Carotenoid Pigment Molecules in Intact Plant Tissues

We report here the detection of resonance Raman (RR)¹⁻¹¹ scattering of laser radiation from vibrational modes in the molecules of the carotenoid pigments¹²⁻¹⁴ lycopene and β -carotene in intact plant samples (Figs. 1a and b). Resonance enhancement is obtained in the Raman spectra of pigments excited at wavelengths in the region of electronic absorption. The effect is manifest in a conspicuous gain in the scattering efficiency from some of the vibrational modes of the pigment. The scattered light becomes sufficiently intense to overcome the increased absorption losses of both the exciting and the scattered radiation. In this study we have demonstrated this effect in heterogeneous (tissue) samples, in which the pigment is just one constituent.

Spectra observed at different excitation frequencies have confirmed the sideband character of the emission lines, so that perhaps the name rigorous resonance Raman effect (RRE)¹¹ more adequately describes our findings¹⁵. Considerations of whether RRE at peak absorption differs from resonance fluorescence are sidestepped¹⁶⁻¹⁸.

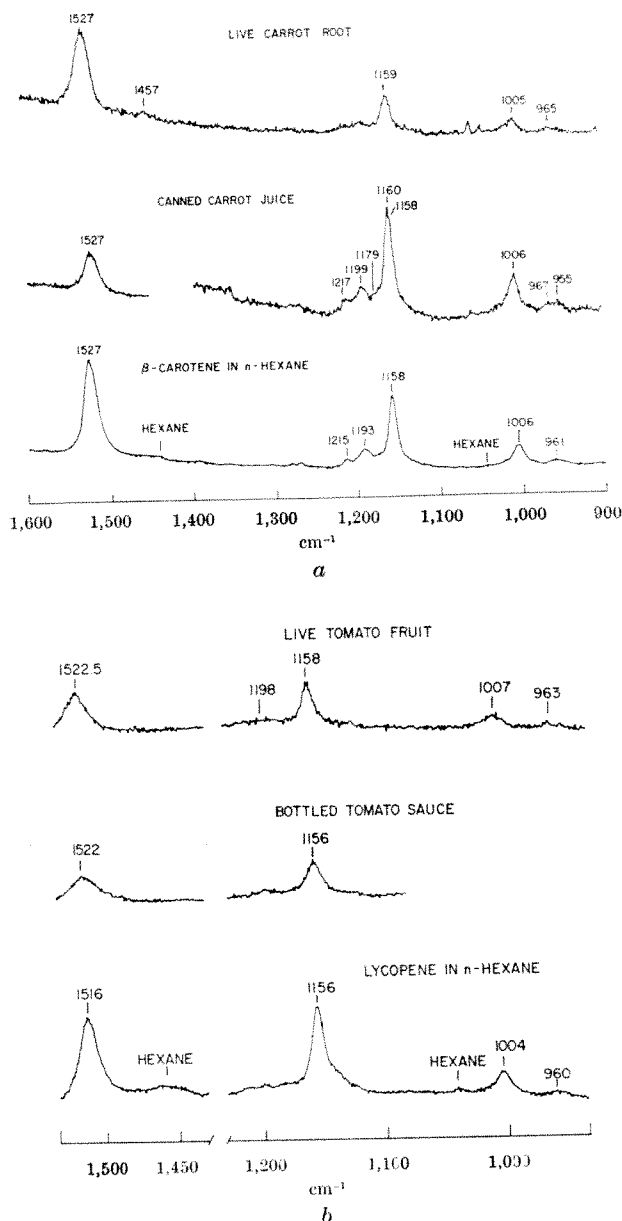

Fig. 1. Vibrational fundamentals in the resonance-enhanced Raman spectra of: (a) β -carotene in live carrot root, in canned carrot juice and the *n*-hexane solution of the pure all-*trans* pigment (Sigma) (excited at 488 nm); (b) lycopene in live tomato fruit, in bottled tomato sauce (the 1527 line of the canned carrot juice spectrum was taken with the gain reduced by a factor of 2) and solutions of lycopene extracted from bottled tomato sauce¹⁹ in an *n*-hexane solution (excited at 5,145 nm). Excitation by argon-ion laser, incident power ~ 100 mW. Grazing angle reflexion geometry: the electric vectors of incident and of analysed scattered light are both perpendicular to the scattering plane. Spectrometer: 75 cm Czerny-Turner double monochromator, digital photon counting detection, integration time 1 s, scanning speed 20 $\text{cm}^{-1}/\text{min}$.

The remarkably intense RR spectra reported for conjugated polyenes in solution¹⁹⁻²² and our study of Raman excitation profiles in carotenoid solutions¹⁵ suggested that RR scatter from pigment molecules in biological samples would be observed without interference from background scattering. Maximum enhancement is obtained in carotenoids, the first absorption band of which is centred within the spectral range of the argon laser emissions. Before the work on live tissues was commenced, light at any one of the frequencies available from the argon-ion laser was scattered from solutions of the pigments in *n*-hexane. By using the Raman lines of hexane as internal standards of intensity, the excitation profiles of the pigments in solution were determined, yielding the wavelengths for optimal excitation¹⁵.

The laser beam impinged at a grazing angle on the surface of the sample facing the collector lens. This applied to solid and fluid samples alike²³. The scattered light was resolved in a double monochromator, then detected in a photomultiplier and processed in digital photon counting circuitry. We have examined the samples listed in Fig. 1. The surprisingly intense RR spectra from the tissue samples give information on the pigment molecules and on their environment. The information content of RR spectra is different and probably greater than that of absorption or luminescence spectra because different selection rules are obeyed. The RR-active chromophore can therefore be added to the list of biophysical reporter groups²⁴⁻²⁶.

We summarize here some of the results and conclusions from the work on the live samples (excitation profiles and spectra in solutions are reported elsewhere)¹⁶. First, RR spectra of carotenoid pigments can be readily obtained by scattering laser radiation of appropriate wavelength from live tissue samples. Second, the Raman lines observed are listed below (the $\nu_1, \nu_2 \dots$ notation for fundamentals was adopted from Shorygin *et al.*²⁰⁻²² and extended beyond ν_3). The frequencies corresponding to vibrational modes are given in wavenumbers. Unbracketed frequencies refer to solutions in *n*-hexane; bracketed frequencies refer to tissue samples. For lycopene: $\nu_2 = 1516$ (1522.5); $\nu_1 = 1156$ (1158), ν_1 satellites = 1210, 1200, 1185 (1198); $\nu_4 = 1004$ (1007); $\nu_5 = 960$ (963); $\sim 2\nu_2 = 3030$ (3045); $\sim (\nu_1 + \nu_2) = 2667$ (2672); $\sim 2\nu_1 = 2300$. For β -carotene: $\nu_2 = 1527$ (1527); $\nu_1 = 1158$ (1158), ν_1 satellites = 1215, 1193, 1176 (1217, 1194, 1176); $\nu_4 = 1006$ (1006); $\nu_5 = 961$ (965); $\sim 2\nu_2 = 3048$ (3046); $\sim (\nu_1 + \nu_2) = 2679$ (2680); $\sim 2\nu_1 = 2313$ (2310); $\sim (\nu_1 + \nu_4) = 2163$.

Third, the spectra are rich in harmonic and combination bands, only some of which are reported here. The most intense ones involve the frequency ν_1 . Fourth, significant vibrational frequency shifts have been observed between the hexane solutions and the live tissue and canned samples. We suggest that these shifts are the result of solvent effects and believe that, by studying model compounds, inferences could be drawn on the local environment of the pigment in the live tissue. Fifth, the line widths and shapes for the live samples differ from those for the canned preparations. The fundamental ν_2 is especially sensitive. Sixth, the O-H stretching vibration in water is observable in the live and the canned samples as a broad shoulder centred at $\sim 3,600 \text{ cm}^{-1}$.

The concentration of pigments in these samples is very high, but RR spectroscopy in solution is known to be sensitive to submicromolar concentrations of pigment and the same probably applies to biological samples. Unfortunately, quantitative determinations are extremely difficult in the absence of internal reference lines.

Laser irradiation of pigments in the absorption region cannot be termed non-destructive, and obviously the chemical and isomeric purity of the carotenoids is somewhat impaired. In practice we have observed no deterioration in the Raman and the absorption spectra of the solutions in *n*-hexane after 1 h of laser irradiation. Moist plant tissue like the inner sections of the tomato fruit or fresh carrot endured the radiation better than a half-dry carrot or autumn leaf.

We thank Mr J. L. Parsons and Dr T. Cole of this laboratory and Professor S. Yatsiv, Professor M. Calvin, Dr M. P. Klein, Mr R. A. Bogomolni, Professor Y. R. Shen and Professor B. Rosenberg for their advice.

Algae thrive under Pure CO₂

ATTEMPTS to grow photosynthetic organisms (O₂ producers) in CO₂ have usually used CO₂ as part of a mixture with other gases. Greater concentrations of CO₂ are toxic to plants and decrease their photosynthetic levels through narcotic poisoning or acidification of the cell fluids¹. We do not know any report of plant growth and physiological activities in anaerobic conditions with pure CO₂. The relation of photosynthesis to environmental conditions such as a pure atmosphere of CO₂ and light intensity is of practical interest in, for example, space biology.

We have carried out physiological experiments with the unicellular hot spring acidophilic alga *Cyanidium caldarium* cultured in pure CO₂. The alga was grown in 500 ml. culture flasks with built-in gassing tubes. A double strength of the mineral medium described by Allen², adjusted to pH 2-3 with sulphuric acid, was used in all experiments. The growth flasks were continually agitated (Burrell, wrist-action shaker) inside a hot water bath covered with a thin layer of mineral oil. The temperature was adjusted to 45° C, which is within the optimal range found both in nature³ and in the laboratory⁴. Continuous illumination was provided by eight General Electric cool white fluorescent tubes supplying an intensity of about 450 foot candles. The CO₂ (commercially available by Liquid Carbonic Corp.) was bubbled at a flow rate of about 200 ml./min and was humidified by passage through water. For each CO₂ flask an air control culture was grown (twice filtered laboratory pipe source); otherwise both were treated similarly. Growth value was determined by measuring the packed cell volume in graduated Hopkins centrifuge tubes.

Photosynthetic determinations were made with a 3-5 ml. oxygen electrode chamber which is described by Shugarman and Appleman⁵. The cells used for photosynthetic studies were harvested about 1 h before the measurements were made. Algae cells were flushed for about 5 min with N₂ to remove all dissolved O₂ in the suspension and then incubated at 28°-29° C and illuminated at 4,500 foot candles.

Illustrations for growth and photosynthetic rates of *Cyanidium* grown under CO₂ or air are shown in Fig. 1.

Fig. 1. Growth of *Cyanidium caldarium* (circles) and the photosynthetic rates (histograms) as a function of CO₂ (solid figures) or air (open figures) supply to the cells.

Both the volume of the packed cells and the O₂ production are significantly higher in the CO₂ treated cultures. The growth curves have a low increase of cells during the first few days, then the CO₂ culture shows a marked increase in the growth slope while the air control grows more slowly but with a steady increase. The adaptation period for this alga under pure CO₂ may decrease the growth rates during the first days. The total O₂ production measured after 18 days of CO₂ treatment is more than that of the 6 day culture. Control cells grown under air have more O₂ per packed cells when the culture is younger (6 days) and less in the older culture (18 days).

The evidence for accelerated growth and photosynthesis under pure CO₂ is noteworthy. The optimal growth for *Cyanidium* occurs in relatively low light intensities (350 to 600 foot candles), as reported elsewhere^{6,7}. Allen² stated that when *Cyanidium* was grown aerobically at high light intensities, it lost some pigments and the culture turned yellowish-green. We observed that the photosynthetic rate rises progressively with the increase of light intensity in treatments under CO₂ or air. *Cyanidium* grown on CO₂ or air is still active in O₂ production at great light intensity (more than 7,000 foot candles) and these photosynthetic rates are more elevated than at a smaller intensity. Similar increasing rates of photosynthesis with light intensity in *Cyanidium* were reported by Fukuda⁸, who found the saturation CO₂ concentration (3 per cent) at about 10⁵ lux (about 9,300 foot candles). The *Cyanidium* cells were obtained from Yellowstone hot springs where they grow at a maximum temperature³ of 56° C. Observations by Copeland⁹ suggested that *Cyanidium caldarium* grows at temperatures of 80° C or above, which contradicts another report³ and also our investigations (unpublished data). A gas analysis of the spring volcanic steam showed that, except for water, CO₂ is the main constituent and is more abundant than all the other gases combined¹⁰. We did not add any sugar or other organic compounds to mineral media, and the pure CO₂ cells were grown in a solution saturated with CO₂, while the aerated culture (without supplemental CO₂) could possibly be affected because of a CO₂ deficiency. It was established that this eukaryotic cell (*Cyanidium*) can be adapted to grow in pure CO₂ while the prokaryotes tested (thermophilic blue-green algae) are unable to sur-

vive such treatment. This indicates that the toxicity of CO₂ is a special problem in virtually every case.

We thank all who showed an active interest in the project, especially Dr W. F. Libby; and W. N. Doemel and Dr T. D. Brock for the *Cyanidium* cultures, Dr R. W. Castenholz for the thermophilic blue-green algae and Dr C. A. Schroeder for his equipment. This research was supported by NASA and the US Air Force Office of Scientific Research.

Mutants in Phototaxis of *Dictyostelium discoideum*

ONE of the more interesting behavioural characteristics of the cellular slime mould, *Dictyostelium discoideum*, involves the concerted migration of thousands of amoebae in a pseudoplasmodium or slug towards light. There have been several studies of the phenomenon, and the action spectrum for phototaxis has been shown¹⁻⁴ to have peaks at 425 and 550 nm. The biochemical process by which light energy controls the direction of movement, however, remains unknown. Moreover, the mechanism of locomotion which can carry a 1 mm long slug for several centimetres in a period of 2-3 days is unclear, but seems to involve more than directed amoeboid motion of the individual cells. Because the amoebae in a slug move through a casing of slime secreted as a viscous fluid by the tip cells⁵, it seems probable that both the extent and the direction of migration would be dependent on the rate of formation of slime casing. Because further biochemical analysis might benefit from the availability of mutants which lack the phototactic response, conditions which would make it possible to select such mutant strains were developed.

Single drops of an overnight SM broth culture of *Aerobacter aerogenes*⁶ on 2 per cent washed agar were found to allow inocula of a few *D. discoideum* cells to grow to populations of 5 × 10⁵ to 2 × 10⁶ amoebae. When the amoebae depleted the bacterial food supply, they aggregated and formed up to twenty slugs. If the amoebae were incubated in a light-tight container (a baking pan with aluminium foil was found convenient), the slugs migrated randomly, leaving the depleted drop of bacteria at all points over the 360° of the circle. If, however, visible light was allowed to enter the container through a small hole, the slugs oriented themselves and migrated within an arc of about 30° directly towards the light.

To enrich the population in mutant strains, wild-type cells were treated with the mutagen N'-methyl-N'-nitro-

Fig. 1. Phototactic response of *D. discoideum* strains. Droplets containing 10^7 washed cells of strain NC-4 wild-type (left drop), strain L-20 (centre drop), strain L-25 (right drop) were placed on an agar base in a 9 cm Petri dish and exposed to a point source of light (bottom centre of photograph). After 48 h incubation at 22° C the cells had aggregated to form slugs which migrated out of the drops. The path taken by each slug is clearly marked by slime excreted along the way. The slugs, which are about 1 mm long, can be seen at the ends of the slime trails. Photographed by transmitted light.

N-nitrosoguanidine⁷ and then spread on normal growth plates with bacteria. After incubation for 4 days at 22° C, individual clones of amoebae were picked and inoculated into bacterial drops on a 2 per cent agar base in a light-tight container with three small holes at one end. After incubation in a normally illuminated room at 22° C for 4 days, the isolates were inspected for phototaxis. In all, 614 such isolates were screened. Most of the isolates formed slugs which migrated directly towards the light. Several failed to form slugs while others formed slugs which failed to migrate at all. Two isolates formed normal slugs which then left the bacterial drop over a large sector and migrated in an essentially random manner similar to that of wild-type slugs migrating in the dark. These strains then constructed fruiting bodies which accumulated yellow spore pigment normally. The strains L-20 and L-25 were subcultured and studied further.

Although phototaxis in strain L-20 was clearly abnormal in the above conditions, many slugs of this strain ultimately oriented towards the light source. To determine whether more intense light could increase the orientation, 10^7 washed cells of strains NC-4 (wild-type), L-20 and L-25 were deposited in small drops on an agar surface in a Petri dish painted black except for a small hole. A strong beam of light from a microscope illuminator was directed at the hole about 5 cm away. The wild-type cells formed slugs which migrated directly towards the light while slugs derived from strain L-20 again oriented poorly towards the light (Fig. 1). Slugs derived from strain L-25 migrated in total disregard to the direction of the intense light source.

The pattern of migration seen in Fig. 1 gives the impression that the extent of migration is much smaller in slugs of the mutant strains than in those of the wild-type strain and suggests that the mechanism of locomotion might be impaired in the mutants. It must, however, be remembered that slugs of strain L-25 proceeded on a random walk while those of wild-type NC-4 moved straight towards the light. Slugs of strain L-20 moved on an intermediate path. When the lengths of the slime trails of the mutant strains were followed over their crooked courses, it was found that the slugs had migrated at least half as far as those of the wild-type. It was concluded that the slugs of the mutant strains not only have apparently normal morphology but are also able to migrate in

an essentially normal fashion except for an impairment in phototaxis.

It has been known for several years that small numbers of wild-type cells can interact synergistically with morphological mutant cells of *D. discoideum* to form normal fruiting bodies^{7,8}, and it therefore seemed possible that wild-type cells might lead cells of the blind mutants towards the light. When cells of strain NC-4 were mixed in equal portions with cells of strains L-20 and L-25, however, the phototactic response was only slightly improved. The response seems to be essentially restricted to the individual cells and not transmitted throughout the organism.

Phototaxis in *D. discoideum* has been shown to be effected by the "lens effect" of the translucent cells³. It seems that light is focused on the side of the slug away from the light and preferentially stimulates these cells. It is thus quite possible that these cells are stimulated to produce more of the slime casing and thus turn the slug towards the light.

The isolation of photo-insensitive mutant strains of *D. discoideum* proves that at least certain behavioural attributes of this organism are under direct genetic control. Further studies involving these mutant strains may elucidate the chemical basis of phototaxis.

I thank Yaira Haas for laboratory assistance and William Moller for photographic assistance. This work was supported by the US Atomic Energy Commission.

Lower Cretaceous Fleas

Two fleas have been collected in association with abundant remains of fish, plants, phyllopod Crustacea (Conchostraca, Anostraca and Cladocera) and other insects in a Lower Cretaceous siltstone at Koonwarra, southern Gippsland, Australia. The insect fauna consists mainly of the aquatic immature stages of Ephemeroptera (mayflies), Diptera (midges), Coleoptera (beetles), Plecoptera (stoneflies) and Odonata (dragonflies and damselflies). The aquatic larvae of the scorpionfly family Nannochoristidae (Mecoptera) are also preserved. There is also a small adventitious fauna of adult insects, including the fleas, the immature stages of which are not aquatic. The only known remains of warm-blooded vertebrates are feathers¹.

One flea is of normal pulicid form and size. In many respects it is ancestral to the modern stickfast fleas (*Echidnophaga*), some species of which are endemic on Australian marsupials. This flea has very elongated mouthparts similar to those of the stick-fast fleas.

The second flea (Fig. 1) is most interesting, for it combines a typical flea abdomen and male genitalia with a very primitive head structure. The head is less compressed and the antennae are not markedly shortened and recessed in grooves along the side of the head as in modern fleas; they are prominent although the segments are short and of cone-in-cone form. The legs are unusually long and the tibiae bear pseudocombs of short stout

Fig. 1. One of the Koonwarra fleas.

bristles: the hind femur is not enlarged for jumping. The structure of the legs suggests that this insect lived on a sparsely haired (furred) animal and that it clung to the outer portions of the hairs rather than burrowed between the hairs. The specimen, with a body length of 7 mm, is large as compared with most modern fleas, especially as it is a male: male fleas are distinctly smaller than females. Females of some modern fleas, however, are of this order of size. The nematocerous-type antennae tend to support the more usually accepted conclusion that the fleas evolved from a nematocerous-type ancestor.

The presence of two very different types of fleas or flea-like insects in the Lower Cretaceous, one of which is similar to modern fleas, indicates that the Siphonaptera must have had a long history before the Lower Cretaceous. The more primitive of the two species shows that loss of wings and development of a specialized copulatory mechanism occurred before reduction in nematocerous-like antennae resulted in their being recessed in grooves on the head, and before the development of combs on the head and thorax. The Siphonaptera must have arisen from a primitive nematocerous-like ancestor before specialization of the male terminalia resulted in structures similar to those of modern Nematocera. Undoubted Diptera are recorded from the Triassic. It seems probable that the Siphonaptera evolved from nematocerous Diptera in the Late Triassic or early Jurassic, at about the same time as the first warm blooded vertebrates.

Deductions concerning the ecological association of at least the more primitive of the two species with a furred animal, and not a bird, indicate that marsupials must have been present in Australia at a very much earlier period than has hitherto been conceded, and this species thus sheds new light on the probable centre of origin, and on the early dispersal of the marsupials as it affects the zoogeography of the southern continents.

Taxonomy and Cranial Capacity of Olduvai Hominid 7 (continued)

PILBEAM rejects¹ my recent estimate of cranial capacity for *Homo africanus*². As I understand his comment, he disputes treatment of Olduvai hominid 7 with the South African gracile australopithecines as one statistical population because they may belong to separate subspecies.

The question of how many subspecies may exist within *Homo africanus* was never raised because it is not relevant. Given the possible time span of this taxon, and the nature of many hominid-bearing deposits, the only safe assumption would be that each specimen represents a distinct biological population³. It is for precisely this reason that species are generally the smallest meaningful taxonomic unit for fossil material⁴. When cranial capacity is considered as a species parameter, the specimens representing the species make up the statistical universe. It seems to me that estimations of species parameters are best made if all of the specimens referred to the species are considered. Indeed, Pilbeam seems to contradict himself, supporting the inclusion of Olduvai hominid 7 in "*africanus*" on the basis of cranial capacity, in a paper⁵ published the same month as the comment considered here¹ (October 1969).

It may be added that the use of a *t* test for small sample sizes is misleading. It is not unusual to find relatively high *t* values for the large or small ends of a small sample. For instance, using the published data for *Homo erectus*⁶, the *t* value calculated for the largest *Homo erectus* cranium (skull 10 from Choukoutien) is 2.93 (10 degrees of freedom). This indicates a probability of 0.98 that the largest *Homo erectus* cranium does not differ from the eleven other crania by chance alone. It does not place skull 10 in another species, let alone another genus.

In fact, this result does not even mean that skull 10 is necessarily representative of a separate biological population. The parameters which characterize taxa, whether on subspecies, species or supraspecies levels, can only be derived from the distribution of the actual specimens⁶.

In sum, Pilbeam's criteria for drawing firm taxonomic conclusions have been met in the case of Olduvai hominid 7. There is no morphological evidence in either the dentition or the cranial capacity which justifies, or even suggests, the separation of this specimen from *Homo africanus*.

Early Hominids and Cranial Capacities (continued)

I SHOULD like to make a few points arising from the previous letter¹. Much of the debate centres around the problem of species in palaeontology; how to define these, and how to assign new specimens to their appropriate taxon². It is obvious that "the specimens representing the species make up the statistical universe". The point which Wolpoff ignores is the manner in which individual specimens are assigned to "species". In classifying fossils, due attention must be paid to variation within and between infraspecific populations, as well as to possible variation due to time³. The most important issue to decide in the

evaluation of a new find is the species lineage (that is, a sequence of ancestral/descendant species populations) to which it belongs, and this requires some consideration of position with respect to infraspecific lineages (infraspecific lineages being sequences of ancestral/descendant infraspecific populations which are not isolated from others but which do have some time duration). Only when this decision has been made ought attention to be turned to classification at the species level, that is, to dividing up the evolving continuum and giving the arbitrary divisions binomina.

Although the dating of the South African *Australopithecus africanus* sites (Taung, Sterkfontein and Makapans) is far from accurate, there is some agreement that they are sampling a time period in excess of 2 million years³. Although it is obvious that each specimen represents a population, this is not the point I was trying to make. The specimens from Sterkfontein, for example, probably cover a relatively short period of time, and it is very likely that they are sampled from one infraspecific lineage of hominids living in that area. In the parameter under consideration, cranial capacity, they show only a small range of variation, four specimens⁴ varying between 428 cm³ and 485 cm³. It is generally agreed that Makapans is a little younger than Sterkfontein. One estimate of cranial capacity is available from Makapans, 435 cm³. Morphologically, the specimen is very similar to those from Sterkfontein⁵. The status of the Taung infant, of uncertain geological age, is more equivocal, but at present it can be assumed that it is sampled from the same species lineage, and very probably the same infraspecific lineage; its inferred adult cranial capacity⁴ is 440 cm³. The range for the six values for *A. africanus* is 57 cm³ (428–485), and the coefficient of variation (corrected for sample size) is only 5.2.

The same taxon, *A. africanus*, is apparently represented in deposits in the Omo region of Ethiopia which range in age from a little under 2 million to a little under 4 million years⁶. At present, reported material consists only of teeth and jaws. There are only minor differences between the Omo and South African samples (particularly Sterkfontein) and it seems reasonable to assume that the samples represent geographical variants of the same species lineage drawn from approximately the same period of late Cenozoic time. It is also reasonable to include all specimens within the same arbitrary segment (palaeospecies) of this lineage, and describe them all as *A. africanus*⁶. (I prefer this generic designation to *Homo africanus* for reasons outlined elsewhere⁷.)

In considering the position of Olduvai hominid 7, the first question to ask is "To which lineage does the specimen belong?". The age of this specimen is known (approximately 1.75 million years), and it is therefore younger than both Omo and, if the assumptions are correct, the three South African sites. Dental, gnathic and postcranial evidence suggests that hominid 7, together with other specimens from Olduvai Bed 1 which apparently sample an East African infraspecific lineage younger than 2 million years old, are drawn from a later part of the same species lineage as is represented at Omo, Sterkfontein,

Fig. 1. Samples 1 to 5 are drawn at random from a group of twenty chimpanzees. Sample 6 shows the distribution of *A. africanus* and hominid 7 from Olduvai Bed 1.

Fig. 2. Samples 1 to 5 are taken from a group of twenty chimpanzees (dots) and twenty gorillas (crosses). Sample 6 shows the distribution of *A. africanus* and hominid 7 from Olduvai Bed 1.

Makapans and Taung. There is a distinct possibility though that there has been evolutionary change in this lineage in at least one parameter, cranial capacity, as can be seen by comparing the value for hominid 7 (657 cm³) with those from South Africa (\bar{x} = 442 cm³, s = 22 cm³, o.r. 428–485 cm³, V_{cor} = 5.2, for n = 6)⁴. Using the t test, the only appropriate statistical test available, hominid 7 differs very significantly from the South African sample⁴ (contra statements in ref. 7, which were based on earlier and less accurate volume estimates^{8,9}). Other cranial capacity estimates are available for Olduvai hominids younger than 2 million years, and give values of at least 600 cm³. It would seem, on admittedly sparse evidence, that the differences are unlikely to result from sampling error, but rather reflect evolutionary change in this parameter.

There is another, more empirical approach which can be taken. The differences between hominid 7 and the six *A. africanus* estimates might arise from sampling error. Accordingly, I have taken a series of twenty male and female chimpanzees of known cranial capacity and, using random numbers, extracted samples of seven individuals and examined the pattern of distribution of these. Twenty such samples were taken, and a random selection of five of these distributions is shown in Fig. 1. None of them resembles the pattern exhibited by Olduvai hominid 7 and the six *A. africanus* specimens. A similar procedure was adopted in which six individuals were selected at random from the chimpanzee group together with one individual from a group of twenty male and female gorillas. Twenty such samples were taken, and five of them are shown in Fig. 2. These distributions resemble that of the fossil hominids rather more than do the samples of chimpanzees only. Hominid 7 still appears, however, to differ more from the six known *A. africanus* than does any one gorilla drawn at random from any random sample of six chimpanzees. Once again the evidence would indicate that, on the basis of cranial capacity, hominid 7 differs as much from earlier hominids as does the gorilla from the chimpanzee. It would seem most reasonable, therefore, not to include hominid 7 in *A. africanus*, but to refer it to another species of the genus *Australopithecus*⁷.

DIET IN VICTORIAN TIMES

The Dietary Surveys of Dr Edward Smith 1862-3

A New Assessment. By T. C. Barker, D. J. Oddy and John Rudkin. (Occasional Paper No. 1.) Pp. 62+3 plates. (Staples, for the Department of Nutrition, Queen Elizabeth College, London: London, March 1970.) 12s 6d.

THIS is the first of a series of papers from an interdisciplinary group which meets three or four times a year at Queen Elizabeth College, London, to discuss the development of diet and food habits in this country. This collaboration between economic historians, social scientists and nutritionists will, it is hoped, throw more light on why people eat what they do, and the effect on their health. An assessment is made of the nutritional value of the diets Dr Smith collected in the early 1860s, comparing them with Boyd Orr's findings in the 1930s and with the position for lower income groups in 1965. Some conclusions are drawn on the relationship of particular dietary features, such as the intake of sugar, fat and calcium, with certain diseases. The study begins and ends with comments on the life and career of Dr Edward Smith himself, and a bibliography of his publications.

Listed in this way this work sounds impressive. Yet it leaves the reader dissatisfied and with an unfortunate impression of being too slight. Perhaps this is because the most interesting questions cannot be followed up in this publication. The authors' purpose will be served, however, if their work creates further interest in an analysis of historical data using modern techniques to assess the quality of the diet consumed.

Dr Smith seems an interesting man, another of those public spirited Victorians who found his environment wanting, especially for others less fortunate than himself. He was an uncomfortable ally and it would be interesting to know more of the nature of the quarrel he had with Sir John Simon, whose department under the Local Government Board created in 1871 absorbed Smith's work as Medical Officer to the Poor Law Board.

There are some aspects of the comparative sections of this discussion on Smith's survey which appear hasty and incomplete—the comparison, for example, between the wage material collected by James Caird in 1850-51 and Smith's data on the rural labourer. The limitations of Smith's own work are, however, more carefully explained, especially its coverage of certain types of indoor workers—silk-weavers, needlewomen, glovers and shoemakers, as well as some rural labourers. He also interviewed cotton workers during the depression of the early 1860s, and compared their diets with those they had enjoyed before the American Civil War. The nutritional analysis is done with the same care; the calories and nutrients have been calculated by computer from tables of food composition, making allowances for differences between nineteenth and twentieth century foods, such as bread. The vitamin content has not been measured because of the hazards of various processes of preservation and cooking. On the other hand, some comment on the possible deficiencies in vitamin intake would have been helpful in an assessment of diets containing so few vegetables other than potatoes and little fruit.

The indoor workers in Smith's sample, excluding the

cotton workers, seem to have enjoyed a poorer diet than rural labourers, especially in calories, protein, iron and calcium. In the past hundred years there has been a large fall in bread consumption resulting in a reduction in calories, but compensated for by a rise in consumption of milk, meat, fat and potatoes. There are difficulties in assessing the way in which foods were distributed between members of the family, but the authors conclude that the quality of diet in the 1860s must have affected work efficiency adversely.

Some interesting observations are made on the effect of a reduction in family income on diet. Cuts in expenditure during the cotton famine were made on all foods, and not just on the quality items, largely to maintain palatability, it is suggested. Yet the reductions in meat and fats were particularly severe, and bread was rendered palatable by spreading more treacle on it. The retention of a high level of sweet substances particularly interests the authors, as does the very large increase in sugar consumption of the past hundred years and the possible connexion between this and coronary thrombosis. Their other comments on the relationship between diet and disease concern the calcium intake; yet it seems rather a lavish claim from the evidence given in this publication to suggest that the low intake of calcium in the 1860s among the cotton workers was not matched by any clinical evidence of calcium-deficiency diseases. It seems that the general effect of the impoverished diet of the mid-nineteenth century, made worse by the cotton famine, was an impairment of resistance to infectious diseases such as typhus, whooping cough, chicken pox, scarlet fever, and possibly to diseases such as tuberculosis.

JANET BLACKMAN

SEEKERS OF NATURE

The Eternal Quest

The Story of the Great Naturalists. By Alexander B. Adams. Pp. 509+12 plates. (Constable: London, June 1970.) 70s.

ANY attempt to survey the progress of knowledge in the natural sciences is a formidable undertaking. Within the confines of a single volume it represents an exercise in selection and compression, which inevitably invites criticism for omissions or emphasis. Mr Alexander Adams succeeds in his declared objective of writing the story of man's discovery of his place in the natural world and to show the qualities and characters of some of the men who made these discoveries.

The Eternal Quest opens with Aristotle, his teachings, especially his observational approach, and critical appraisal of all scientific concepts, and strangely Pliny the Elder, arch-compiler and encyclopaedist of the first century AD. Succeeding essays tell in narrative of the contributions of Copernicus, Vesalius, Bruno, Kepler, Newton and others to the progress of scientific thought. With a more detailed review of the work of Linnaeus the emphasis turns to the naturalists, in the modern meaning of the word. Here the acclaim given to Linnaeus's system of classification is probably overdone. Great as Linnaeus's contribution to natural history was, his classification and the concept of binominal nomenclature owed much (perhaps more than he acknowledged) to John Ray and Peter Artedi. Both are mentioned in this book, but their contribution to the development of Linnaeus's method is surprisingly not.

From Linnaeus the book turns to the work of Buffon, Lamarck, Cuvier, and the latter's pupil Louis Agassiz, whose early work on glaciers and fossil fishes led him to a position of great influence especially in the United States. The life and work of Alexander Wilson, the "father of American Ornithology", son of a Scottish smuggler, and himself a forced emigrant from Scotland who, although

desperately poor all his life, devoted his slender resources, great energy and genius to the production of his *American Ornithology*. Audubon, his successor, is naturally included (for Adams is the author of a definitive study, *John James Audubon* (1967)). Humboldt, Lyell, Darwin, Wallace, Huxley and Mendel bring the history up to the beginning of the present century.

The personalities of these naturalists were so different that this study makes a fascinating human document. Some were modest, some arrogant, but all were driven by an invisible demon of discontent with accepted ideas, and were therefore continually searching for a tenable position. Whatever one's personal quibbles over the omission of some favourite naturalist, Adams's *Eternal Quest* is a "wide screen" treatment of the development of natural history, giving a balanced and broad picture of absorbing interest to the general reader and an introduction to the subject.

ALWYNE WHEELER

SCIENCE FOR SCHOOLS

Nuffield Combined Science Pack 1

Activities—Book 1: Pp. 72; Book 2: Pp. 66; Book 3: Pp. 40; Book 4: Pp. 47; Book 5: Pp. 36. Reference Sheets: Pp. 27. Teachers' Guide 1 (Sections 1–5): Pp. xxiii + 411. Teachers' Guide 3: Pp. vii + 266. (Longman: London; Penguin: Harmondsworth, Middlesex, 1970.) n.p.

THIS is the first batch of materials for use with the new *Nuffield Combined Science* course for 11 to 13-year-olds. *Teachers' Guide 2* and five more *Activities* booklets will complete the set.

Any attempt at really integrating the various branches of scientific knowledge so that the product is satisfying for both teacher and taught faces major problems. These problems are concentrated in the selection of material and its presentation in such a way that the users do not get the feeling of hopping haphazardly from one topic to another. In general, the four authors of this course can feel reasonably satisfied with their efforts at coherence and clear presentation. It is instructive to compare the Nuffield course with two other attempts at integration: the *Science Worksheets* prepared by the Scottish Secondary Science Working Party (published by Heinemann Educational Books), and Professor Harry Messel's *Science for High School Students* (University of Sydney). There are many similarities in the outlook and approach of the three groups and also in their choice of experimental and illustrative material.

The important thing about any new course is how the consumers react to it. The trials for this one involved thirty-five schools, eighty teachers, and three thousand children; and, making an allowance for the inevitable Hawthorne effect, there is good evidence that the materials were well received. *Teachers' Guide 1* quotes many comments (not all of them complimentary) from the teachers involved. The authors claim that the course can be adapted for use with the whole range of ability, and there is a useful appendix consisting of comments from teachers who used it with slow learners.

The authors of the *Teachers' Guides* successfully walk the tightrope between appearing to be dogmatic and definitive (so cramping the originality of the teacher), and failing to give adequate guidance to those many teachers who will have to deal with topics outside the range of their personal knowledge. *Teachers' Guide 3* is a reference book: full of useful hints, details of apparatus, materials, and teaching aids, with a mathematics appendix. *Teachers' Guide 1* ties in with the *Activities* booklets for the pupils. Both *Guide* and booklets are well illustrated, and the instructions are detailed without being fussy. The booklets are clear and readable, but will probably have to be treated as expendable. The *Guide* contains

some excellent educational philosophy; the introduction to the section on "Looking for Patterns" is particularly impressive. There is a welcome emphasis on doing simple experiments at home; and in places one can detect the influence of that seminal classic, UNESCO's *Source Book for Science Teaching*.

There are three major limitations to curriculum innovation in science: the capacity of the teachers, the time allocated within the school curriculum, and money. This particular course is intended to be taught by one teacher throughout. I, for one, could not do it without an extensive period of in-service training; for example, how many physics and chemistry teachers would back themselves to dissect a rat properly, even with full printed and photographic instructions? Also, there is currently an absolute shortage of science teachers, particularly for the physical sciences (*vide* the Royal Society's recent report). The Nuffield group suggests that this course should occupy five periods per week. I would regard this as an absolute minimum; but many headmasters and more particularly headmistresses would think it too much, especially for the first year. The authors also warn that the costs of the *Nuffield Combined Science* are likely to be higher than for some other schemes.

All those concerned with the teaching of science in the early secondary years should give serious considerations to these books.

MARTYN BERRY

ISLAND RIDDLES

Serendipity in St Helena

A Genetical and Medical Study of an Isolated Community. By Ian Shine, with the assistance of Reynold Gold. Pp. xv + 187. (Pergamon: Oxford and New York, 1970.) n.p.

EPIDEMIOLOGISTS are said to plan their studies by first defining their population, and there are few studies whose success has turned upon the chance discovery of a population. Such, however, was the good fortune of the author of this monograph who found himself, by chance, medical officer to a remarkable island population. The ancestors of St Helena's population today were Europeans, Indians, Africans and Chinese who arrived voluntarily or by force and who have interbred over the past three hundred years to a remarkable extent. The 4,642 men, women and children who live there today consequently form a uniquely interbred and even inbred mixture of races in whom the pattern of disease might be expected to be unusual. The author's survey by examination and questioning of ninety per cent of the population did, in fact, bring to light an unusually high incidence of some rare congenital disorders, though it also showed the islanders to be remarkably healthy. Not all the author's findings are analysed in this monograph, which deals largely with the incidence of congenital defects of a structural or metabolic type and with a study of eighty-seven consanguineously derived propositi and of a similar number of non-inbred controls.

Having found that the incidence of albinism, deaf mutism, mongolism, Christmas disease, microphthalmia and some other rare defects was remarkably high compared with that in other studies, the author remained unable to explain his results. Inbreeding provided him with part explanation, but it was not enough to account for the high frequency of recessive traits. Migration from the island, genetic drift, selection and mutation were all considered and found inadequate on the basis of current knowledge. The resulting conundrum posed by the author will be a challenge to others interested in population genetics.

Taken all-in-all, the St Helenians seem to be a happy race, though they suffer from asthma to an unusual extent, from ischaemic heart disease in spite of walking habitually, and from hallux valgus. Only in the case of the latter can the disease be clearly attributed to the environment—namely to wearing shoes.

CHARLES STUART-HARRIS

GENETIC COMPLEMENTATION

Molecular Biology and the Origin of Species

Heterosis, Protein Polymorphism and Animal Breeding. By Clyde Manwell and C. M. Ann Baker. (Biology Series.) Pp. xiv + 394. (Sidgwick and Jackson: London, April 1970.) 80s boards; 25s paper.

This book has grown out of the authors' researches into the protein polymorphisms of marine organisms and of poultry, which are here set in the context of related studies and organized around two central concepts; the origin of species, and the use of hybrid vigour in animal and plant breeding. (For good measure, there is also a half-topic, so to speak, on pollution as an evolutionary force.) Although this means that we get two books for the price of one, we have to pay for it: parts of the book are written for breeders, whereas other parts have molecular biologists in mind; and this ambiguity of purpose, and an involved style, make the text difficult to read. Nevertheless, because about 1,000 papers are reviewed, there is much of interest to be gleaned; so it is unfortunate that the index is not organized to this end.

The business of the book is heterosis (hybrid vigour), defined as positive when the hybrid is superior to both parents (following East and Jones), or negative when it is inferior (following Stern, but inverting East and Jones). It is argued that the molecular basis of both is "complementation, either between different polypeptide chains in a protein with a quaternary structure, or between functionally related proteins in a metabolic pathway". These very different possibilities are often confused, and much of the text is given over to explaining the physical chemistry of protein structure and the molecular basis of complementation. The literature on the proteins of heterozygotes is thoroughly reviewed, but the arrangement of the chapters leads to some repetition, and the relevance of a point often becomes clear only in the later chapters when the occurrence of hybrid proteins is related to heterosis. Theory and results are then pushed to their limits (sometimes with the aid of incorrectly computed statistical tests), to "prove" the correlation between complementation and hybrid vigour, positive or negative. After all this it comes almost as a surprise to find that the authors view the successes of hybrid breeding with some scepticism. Their criticisms are not new, but it is useful to have them brought together in one place. The breeder may be forgiven, however, if he is similarly sceptical about their prescriptions for the future: "quantitative genetics for animal breeding will combine not only the mathematics of populations and selection but also the mathematics of allosteric effects and reaction rates". He will remember, if he is a poultry breeder, that blood group polymorphisms were once recommended as sure guides to breeding success. But not any more.

The tabulations in this book suggest that "negative" heterosis is common, and this has to be explained. At least in some instances, the reason is that the samples are too small to give reliable estimates of the deficit of heterozygotes found in a population (for example Table 12), and the reader should be reminded that Raymond Pearl laid down strict rules for the proof of selection of particular genotypes, which are not usually satisfied by the data presented. Of course, selective hybrid elimination is well known, but I take it that the authors mean more than this when they cite "negative heterosis as the internal driving force for speciation", namely, heterozygote disadvantage deriving from particular complementing genes. The case for this concept is not rigorously proven.

Heterosis is usually taken to mean the greater vigour of hybrids in terms of growth, survival and fertility. All of these characters are controlled by many genes, and explanations of this vigour which rest on the characteristics of heterozygous alleles (overdominance), or of complementing alleles, are likely to be suspect. There are

no good examples of overdominance, and there is nothing very new about inter-allelic complementation. None the less, the reader who perseveres with this book will find it useful to have an old problem looked at from a new point of view. But it will be hard work for breeders. The book is well produced, and the paperback edition is remarkably inexpensive.

JAMES H. SANG

BONE PHYSIOLOGY

The Physiology of Bone

By Janet M. Vaughan. Pp. xix + 325. (Clarendon Press: Oxford; Oxford University Press: London, April 1970.) 100s boards; 50s paper.

SINGLE author textbooks become rarer and rarer, but, as they do, their merits become more obvious. One author cannot be an expert in everything. Treatment in great depth becomes easier when twenty authors divide up a small field into twenty even smaller parcels, but the gain in depth is often offset by overlapping or even contradiction between different contributors and a patchwork effect which detracts from the overall value and readability of the work.

This is not to decry the value of multiple author books but simply to emphasize that works by single authors, when well done, are characterized by an internal harmony and rhythm which enhance their value and the pleasure that can be derived from them. This volume is an excellent example of the species. Written with the judgment that comes from honourable retirement, produced so fast that it is uniformly up to date, and illustrated with exceptional clarity, it will be well received by workers in the calcium field and will no doubt run to as many editions as the author has the strength to produce.

Bone physiology is not a well defined field and this first book on the subject is therefore a trend-setter. The decision as to what should or should not be included under this title must be an arbitrary one, the choice influenced by the inclinations of the writer. Dame Janet Vaughan has chosen well. The principal chapters cover the structure, function and blood supply of bone and cartilage and their constituent cells, as well as the chemistry of the mineralized and non-mineralized components and the mechanism of calcification. She then proceeds to the flow of the relevant ions through the body fluids and in and out of bone, and discusses the hormones and other factors which influence these homeostatic processes. She dwells lightly on pathological conditions, reviews the relevant vitamins and concludes with an excellent chapter on the enzymes in bone.

It is a competent performance. The break-up into sections, sub-sections and sub-sub-sections makes for easy reference and the illustrations are not only profuse and excellently reproduced but chosen with admirable skill and judgment. The bibliography is solid without being extravagant or pretentious and creates the definite impression that only useful papers actually consulted by the author have been included.

This does not mean that the internal balance of the work cannot be questioned. Nutritionists might well argue that nutritional aspects of bone metabolism are glossed over and that such an important and relevant organ as the kidney receives rather short shrift. In reply the author has only to point to the title of the work which indicates clearly both its scope and its limitations. Bone is the focus of the work and occupies the author's principal attention throughout. The kidney and the gut, though interesting, are kept firmly in their respective places and those of us whose particular interests lie in this direction are not entitled to complain.

In brief, then, here is a good review of a difficult subject which will serve as a reference work for those already in the field and an excellent introduction for those who have not yet moved into it.

B. E. C. NORDIN

AMERICAN ECOLOGY, 1968

Challenge for Survival

Land, Air and Water for Man in Megalopolis. Edited by Pierre Dansereau, with the assistance of Virginia Weadock. Pp. xii + 235. (Columbia University Press: New York and London, April 1970.) 72s; \$7.95.

Books composed from the papers and discussions of conferences carry built-in handicaps, which only the best of them manage to surmount. This one results from a symposium in April 1968 organized by that distinguished and far-seeing ecologist Pierre Dansereau, at that time senior curator in ecology at the New York Botanical Garden which presented the project with the backing of the National Science Foundation.

It is interesting in European Conservation Year to have this further testimony to the convergence of advanced thinking on ecology applied to the total environment in North America with the lines which have been simultaneously developed on the European side of the Atlantic. The style, both in a wider and a strict sense, is refreshingly different, but the material reviewed and the conclusions reached are parallel and similar even where they are not identical. Dansereau's own scholarly essay goes well beyond its title "Megalopolis: Resources and Prospect". Other contributions, such as Frank E. Egler's "Ecology and Management of the Rural and the Suburban Landscape", follow the line of blending a provocative essay-type review with a somewhat sketchy presentation of fact and a number of practical criticisms and proposals.

Helmut E. Landsberg's "Metropolitan Air Layers and Pollution", George M. Woodwell's "Radioactivity and Fallout: the Model Pollution", and David M. Gates's "Relationship between Plants and Atmosphere", help to provide a slightly more solid raft. Several of the papers have already appeared elsewhere in slightly different form. References to literature are on the light side and there is no index.

Challenge for Survival is to be recommended therefore simply as a stimulating series of loosely connected essays by a group of leading American ecologists and others who have something constructive and coherent to say on the present state of ecology and its immense implications for public affairs. Although, as one of the contributors says, we may in a sense have heard it all before, this is one of the best and most succinct statements, in spite of its obvious unevenness, and it will help as a corrective on some of the aspects which European work tends to neglect.

Americans are good at this sort of thing but, as several of the writers remind us, ecology in the United States has been very backward in rising to its social responsibilities. To a European, however, it is somewhat baffling to see so little result in practice to show for so much lively and persuasive illumination as the American record incessantly adds to itself.

E. M. NICHOLSON

FISH DISEASES

Principal Diseases of Marine Fish and Shellfish

By Carl J. Sindermann. Pp. x + 369. (Academic Press: London and New York, April 1970.) 163s.

INFORMATION about diseases in marine animals is widely distributed through the world literature. Dr Sindermann's book provides an excellent summary of existing knowledge. It is an expansion of two earlier reviews^{1,2}.

The introduction forms the first chapter. Nine hypotheses are given about the role of diseases in the marine environment. Chapter two gives an account of the diseases of marine fishes. A short preliminary section indicates how access to the literature is achieved, followed by sections on microbial diseases, including viruses, bacteria, fungi and Protozoa, diseases caused by helminths and parasitic Crustacea, and, finally, genetic and environmentally

induced abnormalities. The diseases of commercially valuable food fishes are emphasized throughout. Each section is divided into appropriate subsections giving a concise account of the range of diseases. A complete review is not attempted; enough information is provided to enable the reader to appreciate the problems involved and to gain entry to the original literature. Drawings or photographs illustrate representative disease symptoms or organisms. Twenty-seven pages of references conclude the chapter.

The same style is followed in the third chapter on the diseases of shellfish. Mollusca and Crustacea are treated separately. The mollusc section is divided into bivalves, gastropods and cephalopods. The section on bivalves is the most extensive; oysters, mussels, clams, scallops and pearl oysters each get individual consideration. Because of the use of these narrower topics, the account is more comprehensive than that given in the chapter on fish diseases. The Crustacea are divided into three subdivisions, crabs, lobsters and shrimps. Fewer illustrations are provided than in the previous chapter. There are twenty-one pages of references for molluscs and eleven for crustaceans.

A basic review of the range of disease organisms is thus provided in chapters two and three. The treatment is thorough, but not exhaustive. It is not intended to provide a means of identification of disease symptoms or organisms, but it does provide a good introduction to the areas of study.

The remaining chapters deal with six topics of importance in relation to disease in the marine environment. For many readers they will be the most interesting part of the book. The following topics are considered: mortalities of marine animals, with emphasis on the role of disease in North American clupeoid fishes and shellfish, disease and parasite problems in marine aquaria and cultivated marine populations, vertebrate and invertebrate defence mechanisms, the relationship of human diseases to diseases of marine animals, and an assessment of the role of disease in the marine environment. Finally, there is a brief discussion of problems of future studies of diseases in the marine environment. References are given at the end of all chapters. There are author and subject indexes.

PROTECTORS AND SENSITIZERS

Radiation Protection and Sensitization

Edited by Harold Moroson and Marcello Quintiliani. (Proceedings of the Second International Symposium of Radiosensitizing and Radioprotective Drugs, Rome, May 1969.) Pp. xvi + 522. (Taylor and Francis: London, March 1970.) 160s.

THE design of this symposium was good; a discussion of both radiation protection and sensitization together at different levels of organization. Unfortunately, no account of the discussion after the various papers appears in the published proceedings, which consist of five review articles and sixty-eight shorter contributions, some of which are good and some of which are slight.

It is clear that while work on molecular and single cell systems is devoted more to sensitization than to protection, the emphasis in multicellular studies is still on protection. Adams reviews some model radiation chemical and cellular systems in a clear and easily read account, dealing generally with both mechanisms, as does Alexander and his colleagues' review of DNA repair in two different cell systems, mouse lymphoma and *Micrococcus radiodurans*. The section on single cell systems contains a good account from Block, Mulligan, Weidner and Doherty of change from protective to sensitizing effects with substitution in a series of chelat-

ing agents, Sinclair's interesting studies of the opposed effects of hydroxyurea and cysteamine in different phases of the cell cycle, and evidence from Duplan and Fuhrer that mitomycin C can be considered to be a true radiosensitizer of colony forming mouse bone marrow cells.

With multicellular systems, protection studies are dominant. Pihl and Sanner review the protective effects of thiols and disulphides in mammals, and Semenov discusses the non-sulphur containing protective agents. This review is much shorter than the other four and would have been more valuable had it been expanded. Twelve out of seventeen papers on multicellular systems describe protective effects, and the quality of these contributions is uneven, although Sztanyik and Várterész make an interesting attempt to analyse the synergism between the protective actions of 2- β -aminoethylisothiourea (AET) and 5-methoxytryptamine in mice. The group of contributed papers on the pharmacology of protective and sensitizing agents is disappointing.

Kaplan gives an admirable and up to date review of the laboratory and clinical use of the halogenated pyrimidine base radiosensitizers, and the contributed papers on clinical uses contain an excellent account by Hoshino, Nagai, Sato, Sano and Watari of the treatment of malignant gliomas by the combined use of antimetabolites, 5-bromo-deoxyuridine (BUdR) and fractionated radiotherapy.

The book is handsomely produced, as its price would suggest. As all papers begin on the right hand page, there are some empty pages (10 per cent, in fact, are blank or contain only a few lines of references), so that one regrets the omission of any discussion even more. Most of the papers are clearly written, but there is an onus on the editors of volumes containing contributions from those writing in a language not their own to prevent phrases such as "rephlectory vasomotorial disturbances" appearing in print. The book should be useful to those actively working in this field, but the mixed quality of some of its contents make it a less straightforward choice for a general radiobiology library.

JENNIFER SHEWELL

SEAMEC AND ITS JOURNAL

The South-East Asian Journal of Tropical Medicine and Public Health

Vol. 1, No. 1. Quarterly. (Central Coordinating Board for Tropical Medicine and Public Health Project by SEAMEC: 420/6 Rajvithi Road, Bangkok, Thailand, March 1970.) \$6.00 per volume.

THE present trend for closer cooperation between countries belonging to a more or less definable geographical, socio-economic or cultural region is particularly evident in south-east Asia. In that part of the world seven countries (Indonesia, Laos, Malaysia, Philippines, Singapore, South Vietnam and Thailand) have formed a south-east Asian ministers of education organization (SEAMEC) which has its permanent council in Bangkok under the direction of its secretary-general Professor Chamlong Harinasuta.

In 1966 this body set up a regional scheme of medical and public health research and training through the co-operative effort of existing national centres. The funds are provided jointly by the countries themselves and by the United States government. Several conferences, seminars, postgraduate courses and an exchange of scientists have been organized under this scheme. It is believed that this training programme will be more appropriate and less expensive than sending the nationals of the countries involved to institutes and schools in the western world. This should also prevent the brain drain from the developing world to the advanced countries.

Among its many services to the community, SEAMEC has now brought out this new journal on tropical medicine and public health. It contains a foreword by Professor B. G. Macgrath, a statement of the *raison d'être* of the

journal by Professor A. A. Sandosham, its chief editor, and an outline of the SEAMEC's aims, ways and means by Professor Ch. Harinasuta.

The scientific content of the journal is varied, and the subjects range from parasitology and entomology to planning of undergraduate education in south-east Asia. Among the eighteen scientific papers of this issue, many are of particular interest. Parasitology *sensu lato* opens with the recent finding of trypanosomes in Malaysian macaques, their transmission by a local *Triatoma* and consideration of their infectivity to man. Other subjects are: Brugian filariasis in Thailand, attempts to immunize cats with irradiated larvae of *Brugia malayi*, leptospirosis in West Malaysia, and immuno-diagnosis of parasitic infections. Other relevant topics comprise the attempt at control of *Schistosoma spindale*, research on molluscan hosts of *Angiostrongylus cantonensis*, experimental double and triple infection of snails with larval trematodes, fascioliasis in Thailand, technique of permanent mounting of eggs and larvae of helminths, action of diethylearbamazine on rats, and a malaria survey on Bougainville Island. Entomology covers the bionomics of *Anopheles* in the western Pacific and fenthion resistance in *Culex fatigans*. A study on haemoglobin B₂ in West Malaysia, an investigation of nutrition and environment in Iban longhouses in Sarawak, discussion of the use of community health projects for undergraduate medical education and an account of a series of laboratory demonstrations complete this first issue.

One can only admire the initiative, the intelligence and the scientific vigour of the south-east Asian research community gathered under the flag of SEAMEC, and the new journal deserves our best wishes and our active support.

L. J. BRUCE-CHWATT

CRUSTAL DISPLACEMENT

Time and Place in Orogeny

Edited by P. E. Kent, G. E. Satterthwaite and A. M. Spencer. (Special publication No. 3.) Pp. viii + 311. (Geological Society of London: London, 1969.) 150s.

AFTER a century and a half of intensive geological research we are scarcely nearer to a clear assessment of the nature, amount and rate of crustal displacement involved in the evolution of continental areas; this at a time when our knowledge of the displacements within the oceanic crust is progressing by leaps and bounds. It was with the aim of rectifying this situation that the Geological Society of London, together with the Yorkshire Geological Society, invited sixteen authors to present papers at a symposium at Durham in January 1968, entitled "Displacement within Continents". This volume, the first of a three-fold presentation leading to a synthesis of continental displacement within the later Mesozoic and Tertiary orogenic belts, presents the sixteen symposium papers in an attempt to review the problems involved and to define the parameters for measuring displacement.

The volume is divided into three sections. The first of these consists of five contributions dealing with the structural analysis of orogenic belts. These papers deal with aspects ranging from the intractable problem of interpreting deep-seated movements from surface structures to improved methods of constructing realistic horizontal sections through regions of complex structure. An important paper dealing with the measurement of strain and displacement difference from a theoretical standpoint suggests practical methods for determining crustal shortening over the entire width of an orogenic belt. The role of palaeomagnetic studies is highlighted in the final paper of this section.

The second section contains three papers concerned with the correlation and dating of orogenic events. A natural bias towards radiometric dating is admirably foiled by a

definitive and constructive account of the science of geological correlation.

The third and final section contains six papers dealing with individual aspects of the study of orogenic belts. The need for an independent tectonic terminology for orogenic belts is emphasized in a contribution which surveys the variety in orogenic belts. In another the rate of displacement, both vertical and horizontal, is considered. Three papers stressing the anomalous nature of the deeper crust within orogenic belts, both in physicochemical characteristics and in relation to its excessive thickness, suggest possible geophysical methods for determining meaningful models of the displacement within continents.

It is pleasing to see a section devoted to discussion, both that following the reading of the papers at the symposium and also that occurring later as written contributions. This section, which serves as a detailed criticism of individual papers, disappoints only in the paucity of points raised.

In such a collection of papers from a range of authors it is to be expected that not all the contributions rise to the level of the best. *Time and Place in Orogeny* is, however, a volume that few structural geologists and geotectonists can afford to be without, and all will anticipate with considerable interest the publication of the second volume of the trilogy: "Data for Orogenic Studies", the aims and organization of which are laid out at the end of this volume.

R. A. GAYER

ARCH PIONEERS

A Span of Bridges

An Illustrated History. By H. J. Hopkins. Pp. 288. (David and Charles: Newton Abbot, June 1970.) 70s.

THE building of bridges is still an exciting branch of engineering, because the challenges it presents never become stereotyped. No two bridges are exactly the same; each time the problems of wind and water, the lie of the land and the levels of the approaches have to be tackled afresh. Thus the Forth and Severn road bridges, finished within two years of one another, solve apparently identical problems in subtly different ways. The bridge designer also needs an eye for proportion and scale; the finished structure must not only do its job, but must be seen to be doing it. Form and function are, of course, closely related, and there are very few great bridges which do not "look" right, even to the untrained eye.

Professor Hopkins has written an excellent history of the art, the craft and finally the profession of building bridges. It is a story well provided with interesting characters, starting with Vitruvius, whose writings of the first century BC establish beyond doubt that the Romans fully understood the principle of the arch. Just before the French Revolution, Jean-Rodolphe Perronet brought this same principle to perfection with his daringly low arches and slim piers at the Pont de la Concorde in Paris. The doubters, of course, predicted instant collapse as soon as the centre supports were removed, but the bridge stands today.

After Perronet came the iron bridges of the nineteenth century—some were triumphs, like Robert Stephenson's recently damaged Britannia Bridge across the Menai Straits, or Telford's Mythe Bridge at Tewkesbury, and some were well remembered disasters, like the "wondrous bridge across the silvery Tay", as McGonigall just had time to call it in the brief space between completion and collapse. Today the suspension bridge, refined to remove dangerous oscillation and twisting, reigns supreme for large structures. Pre-stressed concrete has taken over for the smaller bridges, and it, too, has its masterpieces. Hopkins picks out for particular praise Robert Maillart's Schwandbach and Salgina bridges, both unbelievably light and elegant structures. He also has a good word for Waterloo Bridge across the Thames, whose designers had

to cope not only with nature and the Blitz, but also Sir Giles Gilbert Scott, an eminent architect thrust on them. Londoners have reason to be grateful for their patience and determination, for one has to go upstream as far as I. K. Brunel's Maidenhead railway bridge for a Thames crossing of comparable distinction.

This book will be enjoyed by sixth-formers, undergraduates and armchair engineers everywhere. It is profusely illustrated and admirably written. My only complaints are the uneven quality of the printing and rather haphazard layout; but these are quibbles.

NIGEL HAWKES

DEFECTS IN CRYSTALS

Crystallography and Crystal Defects

By A. Kelly and G. W. Groves. Pp. xi + 428. (Longman: London, May 1970.) 100s.

THIS lucid and interesting book sets itself the somewhat ambitious task of combining the elements of crystallography, stereographic projection, tensor algebra and elasticity theory and of using these in a thorough study of crystal defects. Moreover, the book is aimed at students as widely separated as postgraduates and first year undergraduates. What is important is that it succeeds to a quite remarkable extent. The introduction takes up the first five chapters (part one plus chapter five), and is concisely and accurately presented. Then follows the development with chapters on glide, dislocations, point defects, twinning, martensitic transformation and crystal boundaries. It is necessarily selective, stressing consistently the crystallographic nature and importance of defects, and is refreshingly clear and direct. I liked particularly the discussion of Peierls force and grain boundaries and the chapters on twinning and martensitic transformation. I was disappointed that the discussion of dislocation core structure was not more closely related to crystallography. The book is particularly complete on subjects which the authors have pioneered (for example, independent slip systems).

This is essentially a text, not a reference book. It will certainly be of interest to postgraduates, though I feel that some undergraduates will find its style a little too brief and lacking in development. The book is excellently produced, has useful problems at the end of each chapter with answers at the back, and several valuable appendices. Wherever possible it avoids mathematical detail. In fact, my only criticism of substance is that it has tried to do too much. Our understanding of the importance of the crystallographic nature of defects in crystals is too incomplete at present to allow a full discussion. In many cases where the importance of crystallography is established, a proper discussion would involve prohibitive mathematical complexity, for example, anisotropic elasticity which is only hinted at in this text. We shall have to wait for an authoritative treatment of the subject. J. W. STEEDS

PARTICLE STATES

Elementary Particle Theory

By A. D. Martin and T. D. Spearman. Pp. xiii + 527. (North Holland: Amsterdam, 1970.) Hfl. 83; 193s; \$22.

THE most useful theoretical concept for the analysis of the dynamics of strong interactions between elementary particles which is available to us at present is the scattering matrix (or S-matrix) element, which may be regarded as the quantum mechanical probability amplitude for scattering from an initial to a final state. The S-matrix element is a function of the external parameters in the process such as energy and angle of scattering, and the hope is that this

functional dependence may be determined by the addition of general postulates such as relativistic invariance and conservation of probability. The most powerful additional hypothesis seems to be one about the singularities of the S-matrix elements considered as analytic functions of their variables, which is suggested by the examination of certain models. When supplemented by the Regge pole description of scattering processes at high energies, these assumptions lead, at the least, to relations between S-matrix elements which can be tested against experiment and may furnish the basis of a complete dynamical theory.

The purpose of this book is to give a development of these topics in the detail suitable for the graduate student intending to do theoretical research in the field. A particular feature is the treatment of the kinematics of the one, two, or more, free particle states in terms of which the S-matrix elements are defined. Because the concepts of quantum field theory do not enter into the scheme outlined earlier, the description of free relativistic particles using field equations has been omitted in favour of an equivalent one, which is based on the notion that a complete set of states for a free elementary particle should form the basis for an irreducible representation of the inhomogeneous Lorentz group. The necessary group representation theory is developed without assuming previous knowledge of the subject in the first half of the book, although, occasionally, objects such as the tensor product symbol have slipped in without a precise definition. Isospin and the discrete symmetries P, C, and T are discussed and applied, but not SU(3).

In the second half of the book, the analytic properties of two particle scattering amplitudes and partial wave amplitudes are discussed. Building on the material of the first half, a detailed treatment of the analyticity and crossing properties of helicity amplitudes for arbitrary spin is given, following the approach of Trueman. An excellent final chapter on Regge poles motivates their introduction and brings the reader to within sight of recent activity on the Veneziano representation and its generalizations. The absence of any field theory means assumptions about analyticity, crossing symmetry and kinematic singularities are not motivated by an examination of Feynman graphs. The beginner must look elsewhere for these.

Sets of useful exercises with hints for their solution are provided at the end of each chapter. Students who master this material will be well equipped to undertake research in this field. The presentation in a uniform notation of the topics covered should also make the book a convenient reference for practising theorists. B. R. POLLARD

REACTOR KINETICS

Space-time Nuclear Reactor Kinetics

By Weston M. Stacey, jun. (Nuclear Science and Technology: a Series of Monographs and Textbooks, Vol. 5.) Pp. vii + 186. (Academic Press: New York and London, December 1969.) 121s.

DURING recent years there has been a considerable amount of technical literature on the subject of spatial reactor kinetics, due largely to the inability of the older point kinetic models to describe the transient behaviour of large power reactors, where spatial effects are of considerable importance. This book provides a useful text that bridges the gaps between the older point kinetic models and the more modern spatial approaches.

The reader is expected to have had a basic grounding in reactor kinetics and physics. A basic knowledge of matrix arrays would be an advantage.

The text begins with the now familiar time dependent group diffusion equations and deals with the spatial finite difference approximations. Modal expansion approximations utilizing matrix methods are evaluated, proceeding

through natural modes, Green's function and synthesis modes. Nodal approximations are then considered in detail. The various methods are compared and their respective advantages and disadvantages are discussed for particular applications.

Numerical integration methods are covered in some detail; these will provide the reader with a good foundation to build on, because many subsequent variations lie in the hands of the user. A good discussion is given of stability truncation errors and computation time.

Variational synthesis methods are introduced to allow the general space-kinetics problem to be approached systematically. This leads to multichannel space-time synthesis which makes more efficient use of a given set of expansion functions, a good example being given to illustrate this technique.

Up to this point the book deals with computational methods for solving the spatially dependent kinetic equations and provides the reader with a good broad introduction. The neutron process is stochastic in nature and chapter 4 covers the use of a forward stochastic model which leads to the use of correlation functions. A theory for backwards stochastic model is given and the Langevin technique is discussed in some detail. This chapter is mathematical, and some knowledge of stochastic functions would assist the reader.

There is a good study of xenon spatial oscillations using linear and non-linear techniques. Control induced xenon spatial oscillations are introduced and their control is illustrated. The last two chapters serve to present a basic theory with which to treat the stability and control of spatial reactor models.

To summarize, the book gives an excellent, though mathematical, approach to the subject of space and time dependent reactor kinetics. It contains numerous useful references which will enable the reader to probe more deeply into the subject and, in general, it fulfils its object of bridging the gap between new and old texts.

ALAN JEBB

KINETIC THEORY OF GASES

The Mathematical Theory of Non-Uniform Gases

An Account of the Kinetic Theory of Viscosity, Thermal Conduction and Diffusion in Gases. By Sydney Chapman and T. G. Cowling. Third edition prepared with the co-operation of D. Burnett. Pp. xxiv + 423. (Cambridge University Press: London, May 1970.) 100s; \$16.

THE first edition of this book appeared in 1939 and immediately established itself as an authoritative work on the kinetic theory of gases. This is the third edition of the book in which the already concise and elegant presentation of the equations and text has been improved by printing in a modern format and adopting a new layout of the text. The work has been the basis for the development of the subject matter since the initial publication of the book. The authors, renowned for their contributions in their respective fields, have been aided by Professor D. Burnett in incorporating the most recent developments in the theory.

The chapter dealing with molecular models with internal energy has been completely rewritten to take into account recent advances. The theory of multiple gas mixtures is dealt with for the first time and warrants a chapter of its own. The discussion of the electromagnetic phenomena of gases has been greatly extended to include major contributions that have taken place in this rapidly changing field since 1952, and includes the Fokker-Planck approach to the Boltzmann equation and the subject of collisionless plasmas. The authors have deemed it necessary to omit some of the subject matter that was in the previous edition, but nothing of substance has been left out.

The revision of this substantial work (essential for all research workers in this field) is wholly welcome. Furthermore, it can be thoroughly recommended for those without a copy of the previous edition in their possession. It is, however, hard to justify bringing one's personal library up to date in view of the small number of changes that have been made to the text.

A. L. T. POWELL

ALGEBRAIC TOPOLOGY

The Topology of Classical Groups and Related Topics

By S. Y. Hussein. Notes on Mathematics and its Applications. Pp. viii+128. (Gordon and Breach: London and New York, February 1970.) 95s; \$11.40.

THIS book is based on notes of lectures first given in 1963 to University of Wisconsin graduate students who had previously undertaken a basic course in algebraic topology. Although the material has been polished up in the writing, the overall impression is still one of lecture notes rather than of a finished work. For example, the book has no index. Thus forewarned, the reader will need pen and paper as a constant companion as he journeys through the book.

In spite of or perhaps because of this, the author covers a lot of ground. In the first chapter fibrations are treated together with universal fibrations and various classification theorems are given. After the start of the second chapter, the author defines the concept of an algebra in a universal fashion (in fact, the whole book is very modern in style). Having done this he is then free to dualize and define a co-algebra and a Hopf algebra. The rest of the chapter is devoted to calculating the homology and cohomology of the classical groups. In chapter three the author considers the homology and cohomology of the classifying spaces and loop spaces of the classical Lie groups. This naturally leads on to Bott periodicity and, finally, in chapter four, to K-theory.

ROGER FENN

MODERN CATALYSIS

Catalysis of Gas Reactions by Metals

By A. J. B. Robertson. Pp. xi+182. (Logos, in association with Elek Books: London, June 1970.) 70s.

THE development of comparatively straightforward techniques for reducing the pressure in a laboratory-sized apparatus to the ultra-high vacuum region has had a stimulating effect on the study of the reactions of metal surfaces with simple gases. The reason for this is that by producing background pressures in this region it has become possible to study a chosen reaction in the complete confidence that the residual gas does not make a significant contribution to the observations. The reliability of the measurements has been of great importance in view of the sometimes unexpected results which have been reported. Dr Robertson is well known for his contributions in this area of research and in his book he has chosen to give prominence to some reactions which have been studied under ultra-high vacuum conditions.

In the first two chapters, which constitute about one third of the book, the evolution of ideas about catalysis is traced from the contributions of Davy and Faraday in the early nineteenth century to modern deductions about the highly selective reactivity of the individual planes present on a surface. Almost all of this discussion and of the contents of the next chapter, which gives a brief account of ultra-high vacuum techniques, should be readily comprehensible by sixth-formers. Beyond this point the book gets noticeably harder, though the liberal use of easily understood diagrams and a lucid exposition should allow much of it to be read with profit by this group and by undergraduates in their first year.

The second half of the book describes the distinctive aspects of the contemporary approach to catalysis. Modern techniques for cleaning and studying metal surfaces are described systematically, though briefly. No doubt deliberately, the author refrains from much comment on the relative importance and contribution of the various techniques he describes. This is a pity, because comment from this authoritative source could have been helpful to the newcomer to the field.

In discussing the theoretical interpretation of the experimental results the most detailed treatment is given to the approach by way of transition state theory. A sensible balance is maintained in this discussion between the generalized treatment of fundamental ideas and the detailed interpretation of particular experiments.

This is a book which I enjoyed reading and which I shall recommend to undergraduates for their first encounter with the modern approach to catalysis. It is, unfortunately, presented at a price at which they cannot reasonably be expected to buy their own copy. R. P. H. GASSER

PERSONAL RELATIVITY

Cosmology

By Jean Charon. Translated from the French by Patrick Moore. (World University Library.) Pp. 256. (Weidenfeld and Nicolson: London, July 1970.) 35s boards; 18s paper.

THIS would be an admirable book if it were not for one chapter in which the author presents a personal view of the implications of the theory of relativity, drawing conclusions which differ markedly from the accepted point of view, and which are founded on an extremely uncertain basis. The first eleven chapters give an informative, readable account of the development of man's ideas about the universe, and if the book were concluded after them I would be glad to recommend it to the many people who are interested in cosmology and astronomy but have no mathematical background.

On the cover of the book, a summary states that "The last chapters discuss the possible meanings of space, time, distance... Some of the author's ideas are new and exciting, and are explained in a way which will appeal to both the beginner and the specialist". This latter claim is far from the truth, because although Charon's ideas will certainly appeal to the beginner who knows no better, the specialist is likely to be infuriated by his glib presentation of a biased and unreliable interpretation of the implications of relativity theory as accepted facts. Any specialist reading this review will doubtless have guessed that a large part of the misconceived chapter to which I have referred hangs on an erroneous interpretation of the so-called "twin paradox" of relativistic time dilation. This is certainly not the place to present a detailed refutation of Charon's reasoning—the specialist is already familiar with this (because it has been known for 50 years that there is no paradoxical situation at all), and the non-specialist would be better referred to a standard introductory text such as *Einstein's Theory of Relativity* by Max Born (Dover, 1962).

Because on balance the harm which might be done by the latter part of this book would probably outweigh any benefit derived from the earlier part, I would not recommend it to anybody completely new to the subject, but for those interested in the history of astronomy, and who have either sufficient knowledge of relativity to be unmoved by chapter 12 or sufficient faith in me to ignore it, I would offer a cautious recommendation, although the same historical ground has been covered by other authors in books which do not misinterpret Einstein's theories.

JOHN GRIBBIN

Correspondence

An Unidentified VLF Station

SIR,—During a search of the VLF portion of the radio spectrum for transmitting stations which might serve as sources of “whistler-mode” signals, we observed a transmission on 14.9 kHz which presented some puzzling propagation effects.

Its origin is unknown, and we have been unable to identify the operating agency or the location of the transmitter itself.

We have plotted the diurnal phase variations of the transmitted frequency for about six months, and, by correlating this information with the sunrise and sunset terminators which produce the major phase variations, we have determined that the signals arrive from the direction of the Gulf of Alaska (about 30° true). The great circle distance from Lower Hutt is indefinite, except that it is more than 8,000 kilometres.

Variations of signal strength suggest that at least a portion of the path is subject to PCA events. The station cannot be in Europe or Africa, or its signals would be received along the short great circle path, which can be readily identified by means of the sunrise–sunset phenomena.

There is some evidence that the frequency is controlled by an oscillator which is corrected daily by reference to an atomic standard.

The station is using one of a group of six frequencies used by an unidentified agency during 1969 to transmit a repetitive sequence of short dashes, similar to the well known Omega format, except that the pattern consisted of six intervals over 3.6 seconds, as against the Omega pattern of eight intervals over ten seconds.

No information on the transmission described, or its “navigational” predecessors, which ceased transmission in January 1970, has been noted in the technical or scientific press, and any information on the existing transmissions on 14.9 kHz known to other scientific workers in this field would be welcomed by this laboratory.

Yours faithfully,

M. C. PROBINE

Topology and Metallurgy

SIR,—In a recent publication¹, L. Barrett and C. Yust review the applications of topology to metallurgy. From it, it is clear that metallurgists have been laggard in using topology: after a pioneering paper by C. S. Smith in 1951 (ref. 2) on the analysis of grain shapes in a polycrystal, only some 15 to 20 of the papers which have been published up to now on this problem, on the sintering process and on the study of interfaces in a two-phase material, have applied topological theorems.

This lack of enthusiasm is really surprising because, by its very nature, topology seems to be a very appropriate tool to deal with metallurgy, a brand of science that proposes the “wary analysis of non-living complexity”³, “a perpetual balancing act between the realistic and the tractable”⁴. As Barrett and Yust put it: “Often mathematics, particularly applied mathematics, is thought of

in terms of analytical formulae yielding quantitative results. (Topology) is of a more qualitative nature, offering newer concepts as the means of describing physical phenomena. . . . These concepts yield a fresh viewpoint and unifying relationships among apparently diverse structures”. In typical metallurgical problems as complex as work-hardening, recrystallization, creep and the like, metallurgists have been so busy—and not very successfully as yet!—looking for analytical formulae that they have overlooked the possibility that perhaps topological relationships were more apt to answer their questions. I do not see any epistemological reason why nature must abhor topology. And in fact I would like to suggest that perhaps nature loves topology, as is shown by what I would call the “topological structure” of one of the most important relationships in physical chemistry, very well known, respected and used by all kinds of metallurgists: Gibbs’s rule of phases.

Gibbs’s rule possesses a striking similarity with Euler’s theorem (which gave rise to the discipline of topology): If we call V the number of vertices, E the number of edges and F the number of faces of a polyhedron, then Euler’s theorem states that $V - E + F = 2$. But if V is now the number of phases, E the number of independent components and F the number of degrees of freedom of a physico-chemical system, Gibbs’s rule states that $V - E + F = 2$.

It can, of course, be said that this similarity is merely an accident, a formal curiosity without any further consequence, and that, besides, Gibbs’s rule is not more than a useful “recipe”, deduced from a system of analytical equations establishing the equilibrium conditions of a system of V phases and E components with F degree of freedom. But the important thing to realize is not how the “recipe” is usually deduced, but its very nature: just as Euler’s theorem makes possible a “geometry without metrics”, Gibbs’s rule permits one to analyse equilibrium without measuring anything. It provides a powerful means of dealing with the many variables of the equilibrium of any complex system. To evaluate how powerful it is, it is enough to try to imagine metallurgy without Gibbs’s phase rule.

Are there many other topological relationships in the realm of metallurgy? According to Barrett and Yust, there are very few, and these do not seem to be as important as Gibbs’s phase rule. This paucity is not strange, because it seems that metallurgists have not been looking very hard for applications of topology to their science.

Abortion Act in Action

SIR,—Since the publication of my letter on May 16 (*Nature*, **226**, 673; 1970) more recent official figures¹ have shown that abortion deaths in 1969 were in fact a little up on 1967, the last full year under the old law.

In England and Wales, 10 deaths were directly attri-

buted to legal therapeutic abortions in 1969, not including 4 registered under the Act as resulting from legal operations after illegal or spontaneous abortions. In addition, 8 deaths "from other underlying causes after legal abortion operations" were registered under the Act. Of the latter, 4 resulted from conditions (congenital heart disease; cancer of rectum; cerebral haemorrhage; acute myocarditis) which were probably the reasons for, rather than the results of, the abortion operations. But the other 4 (3 pulmonary embolisms; 1 respiratory obstruction while recovering from anaesthetic) seem themselves more or less directly attributable to the operation, in the sense that these deaths probably would not have occurred had the pregnancies not been terminated. So there were certainly 10 deaths, and probably 14, resulting from legal abortions in 1969.

Also "a further 25 deaths were classified as directly due to abortions other than under the Act"² so that the total for all abortions (legal, illegal and spontaneous) was certainly 35 and probably up to 39 in 1969, as compared with 34 for 1967. It is true that 1967 seems to have been a good year, since the Registrar General recorded 53 abortion deaths for 1966, and 50 for the transitional year 1968 (4 months under the old law and 8 under the new); but plainly there is here as yet no good evidence of any

dramatic reduction in mortality resulting from the Abortion Act 1967, as has sometimes been claimed.

Blue Streak's Record

SIR.—I should be interested to know by what criterion you judge Blue Streak to be "unreliable" as the first stage of the Europa launcher (*Nature*, 227, 425; 1970). Ten successful firings out of ten seems to me to deserve a slightly kinder description.

Yours faithfully,

R. H. W. BULLOCK

Ministry of Technology,

Prospect House,

100 New Oxford Street, London WC1.

MR BULLOCK is right. Blue Streak is reliable. But there is nothing to modify the assertion in the leading article that it is otherwise unsuitable as a starting point for a comprehensive European space programme.—Editor, *Nature*.

Obituaries

Professor F. T. von Brücke

FRANZ THEODOR VON BRÜCKE, professor of pharmacology and toxicology at the University of Vienna, died on March 24, 1970, at the age of 62, after a short illness.

Brücke's capability for independent research was apparent from a paper on the epiphyseal cartilage of long bones which he published while he was a medical student. His later development was profoundly influenced by such distinguished teachers as Otto Loewi and H. H. Dale, under whose guidance he gained experience in the pharmacology of the central and peripheral autonomic nervous system, an area of research to which he devoted the greater part of his life. It was therefore no accident that he was drawn to the Vienna school of pharmacologists, pioneered by H. H. Meyer and his successors, E. P. Pick and R. Rössler, whom he followed to the chair in 1948.

As early as 1935, Brücke recognized the antagonism of bulbocapnine to some of the central effects of apomorphine, an interesting observation in view of the now established interrelationship between dopamine, apomorphine and bulbocapnine. This led later to studies on the different

patterns of release of epinephrine from the adrenal medulla after electrical stimulation of the hypothalamus and occlusion of the carotid sinus. An observation of far-reaching theoretical importance was that small amounts of acetylcholine, injected into the skin, elicited a pilomotor response, whereas larger amounts abolished the effect of sympathetic stimulation.

Brücke investigated the effect of denervation of the superior cervical ganglion of the cat as manifested in its sensitivity to adrenaline and acetylcholine and in cholinesterase depletion. Investigations into the innervation of the rabbit cardia led him to postulate the presence of adrenergic fibres in the vagus and cholinergic fibres in the splanchnic nerve. The induction of spasm of the rabbit cardia following severance of the vagus proved to be a simple device for the evaluation of spasmolytic agents. Brücke also studied the influence of acidity and basicity on the cardiac glycosides and described the importance of the binding of digitoxin to protein.

With the increase in his administrative responsibilities as chairman of a large research and teaching department, Brücke's own involvement in laboratory work decreased in later years, but he continued to stimulate research among his students and co-workers. His ability to generate enthusiasm attracted talented young investigators who have since taken up important academic positions in Europe, the USA and Canada. Under Brücke's direction the Vienna school embarked on a broad investigation of dicholinesters of dicarboxylic acids as muscle relaxants which led to the introduction of succinylcholine into anaesthesiology. Another line of inquiry initiated by Brücke was the investigation by electroencephalography of hippocampal activity in the rabbit.

Brücke was recognized as an outstanding authority in matters of public health and in his capacity as an adviser to the pharmaceutical industry. His editorship of the *Wiener Klinische Wochenschrift* won for the journal a high reputation; his communications, both oral and written, sparkled with lucidity and wit. It is no exaggeration to say, too, that his acumen and foresight spared his country the ravages of thalidomide.

Announcements

University News

Dr James A. Dunne has been named project scientist at the Jet Propulsion Laboratory, **California Institute of Technology**, for the 1971 Mariner mission to Venus and Mercury.

Mr Bryan Campbell Clarke, University of Edinburgh, has been appointed to the newly established chair of genetics in the **University of Nottingham**.

Appointments

Mr A. Goodson has been appointed head/space in the **Ministry of Technology** in succession to **Mr R. H. W. Bullock**. Mr Bullock has been appointed deputy secretary.

Dr Harold R. Fletcher has retired as Regius keeper of the **Royal Botanic Garden, Edinburgh**. He is succeeded by **Mr Douglas M. Henderson**, formerly principal scientific officer at the Garden.

Mr A. A. Gray, at present a deputy chairman of the **Wellcome Foundation Limited**, will succeed **Sir Michael Perrin** as chairman when Sir Michael retires at the end of this year.

Sir Harry Melville has been appointed chairman of the **Advisory Council on Research and Development for Fuel and Power**, with effect from October 13, in succession to **Sir Charles Sykes** who is retiring.

At the annual meeting of **Rolls-Royce Limited**, two new board members were announced: **Mr Ian Morrow**, vice-president of the Institute of Chartered Accountants of Scotland, will become executive deputy chairman, with his principal interest in financial control; **Lord Beeching** is to be a non-executive director, representing the interest in Rolls-Royce of the Industrial Reorganization Corporation.

Miscellaneous

Dr Riccardo Giacconi, executive vice president of American Science and Engineering Inc., Cambridge, Massachusetts, has been nominated for the **Röntgen award in astrophysics** by the Physikalisch-Medizinische Gesellschaft, Würzburg. Dr Giacconi is cited for his contributions to X-ray astronomy, including the discovery of X-ray stars and the development of the instrumentation and spacecraft systems required for their observation.

Recent awards announced by the **Academy of Sciences of the USSR** include: the **Vavilov gold medal** for 1970, awarded to **Petr Petrovich Feofilov** for his work on spectroscopy and luminescence of activated crystals; the **Chaplygin Prize for 1970**, awarded to **Samvel Samvelovich Grigoryan** (of the Moscow University Institute of Mechanical Sciences) for his work on mathematical models of explosions in soil and bedrock; and the **Dokuchaev Prize for 1970**, awarded to **Dr Tat'yana Vyacheslavovna Aristovskaya** (of the V. V. Dokuchaev Central Museum of Pedology) for her monograph *Microbiology of Podzolic Soils*, published in 1965.

ERRATUM. In the contents list for the issue of August 1 (*Nature*, 227, xv; 1970), the entry for page 493 should read:

Transmitter release—Characteristics for squid ganglion similar to those for frog neuromuscular junction—**LESTER** (Rockefeller and Woods Hole).

ERRATUM. In the report "Five Hundred Years After" (*Nature*, 227, 541; 1970) the second line should read "the birth of Mikolaj Kopernik, known to the world"

HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one copy of NATURE each week is:

12 MONTHS (52 issues and 4 indexes)

Great Britain and Eire.....	£14 0 0 each
United States of America..... (by air freight).....	\$48 each
Canada..... (by air freight).....	\$52 each
Elsewhere overseas by surface mail.....	£14 0 0 each

(Charge for delivery by air mail on application)

*Shorter periods *pro rata*. (Minimum three months.)

Preparing for the Deluge

WITH all the heady excitement that went with the negotiation and signature of the Non-Proliferation Treaty, it might have been expected that the International Atomic Energy Agency at Vienna would have been transformed and even galvanized into unwonted activity. There is very little tangible sign of this in the annual report of the agency to the end of June and in the budget for 1971 and the accompanying programme which, sensibly enough, the agency has also published in anticipation of the meeting of the governors in September. To be sure, both documents are suffused with a sense of excitement of how different things will be in 1973, when the work load occasioned by the Non-Proliferation Treaty will lie squarely on the agency's shoulders. Outsiders may be forgiven for asking whether the agency is yet sufficiently aware of how different things will then have to be. Is there any hope that the monitoring of the Non-Proliferation Treaty can be carried out by a safeguards organization obtained by simple extrapolation from that which the agency uses at present for the inspection of the nuclear reactors voluntarily submitted to its care? Over the years, the scale of operations has grown steadily. In 1971, the agency expects to have 184 nuclear installations on its book compared with 156 in the current year and 130 in 1969. To be sure, research reactors and other such facilities still make up the bulk of the work. Next year, there will be 30 nuclear power stations to inspect, an increase of four. In the year to the end of June, the agency carried out 91 actual inspections of working installations, a mere 45 per cent of those which might have been carried out. Experience has shown that one inspection occupies an inspector for five days and that, in the year just past, an average of 1.6 inspectors is needed for each inspection, but the agency estimates that in the future its men will be kept more fully occupied as the machinery with which they have to deal becomes more complicated. The forward budget includes some wistful figuring about the likely productivity of the inspectors—the target seems to be about 100 MW per man year. The trouble, which must now be painfully apparent to everybody concerned, is that anything like a full blown inspection of the Non-Proliferation Treaty would require the mobilization of a small army of inspectors. The new budget does sensibly allocate some of the time of the inspectorate to training, but the accumulation of expertise likely to result will not match the need which full safeguards for the treaty will dictate.

This, no doubt, is why the agency seems to have put a great deal of faith in the work of the Committee

on Safeguards set up in June this year to hammer out the principles on which the inspection necessary for the Non-Proliferation Treaty should be carried out. By all accounts, the committee has singled out as one of its objectives the devising of a set of principles that will give the international agency a particular incentive to look closely at the nuclear operations of countries about to cross the threshold at which they might become nuclear powers in the military sense without letting them feel unfairly discriminated against. That is sensible enough as an objective, although it is important to acknowledge that a set of safeguards devised on lines like these is bound to vest in the international agency a degree of political responsibility that will lie uneasily with its present substantially judicial function. In short, it will have to be possible for the agency to turn particular attention, as circumstances change, from one group of countries to another. Is this the kind of role that international civil servants can assume? Or will there have to be some political forum in which decisions can be made about the points at which the safeguards agency should direct attention? Either way, the outlook is not particularly cheerful. The safeguards committee will need all the ingenuity it can muster to surmount merely this obstacle. Goodness knows what will happen when it comes to a decision about the cost of the safeguards operation and the partition of this among the signatories to the treaty. After all, it would seem to be grossly unfair that the nuclear powers immune from inspection under the terms of the treaty should be charged nothing for the cost of operating the safeguards procedure. On the other hand, small countries with no nuclear pretensions and not even a research reactor to call their own rightly feel hard done by to be asked to help to foot the bill. Before the committee's work is done, it will find itself counting the angels on the head of a pin.

In circumstances like these, it is not unacceptably smug to recall that the Non-Proliferation Treaty as a whole is more like an expression of good intention than an assurance that evil things will go away. Now that more than a score of countries have ratified it, and even nations like India are prepared to join in the argument about how it should be implemented for fear that too much insistence on the sovereign right to be a nuclear power will deprive them of a voice, there may be something in the view that even if the Non-Proliferation Treaty is not a guarantee, it is at least an attitude of mind. From that point of view, nobody should worry much if the IAEA's Committee on Safeguards is still in session in 1972—the important

thing will be that they are still talking. But there is of course a danger that too literal an interpretation of the expectation of those who sign the treaty may lead them, by then, to attempt more than they can possibly

accomplish. Not merely will that be bad for the Non-Proliferation Treaty but it will be disastrous for the IAEA. Falling flat on the face is not good for the public image.

Close Season for Technology

THE belief that Mr John Davies, the new Minister of Technology, would be in like a lion and out, quickly, like a wounded rabbit seems well on the way to frustration. So far, very little has been heard from him. To be sure, the holidays have now seized the government, and even the Secretary for Employment and Productivity, Mr Robert Carr, having uttered a gloomy warning about the prospects for the economy, has himself gone on vacation. But even if the Bank of England can be relied upon to manage the financial affairs of Britain in high vacation, it is beyond a joke that nobody should have acknowledged that a decade has passed since the need was first recognized for a radical reorganization of the government research establishments. And it is not merely sad but also destructive of people's confidence that the previous government's attempt either to solve or to conceal the problems of the research establishments, in Mr Wedgwood Benn's green paper, should have been allowed to lapse without replacement. Mr Davies, Mr Carr and even the Prime Minister might occasionally remember, while relaxing on their vacations, that a great many of those who work in government establishments are spending less comfortable vacations. Some of them may even be wondering whether they will have jobs to which to return.

So far, the new government (in the person of Mr Geoffrey Rippon, the five weeks' minister) is committed to producing a bill to set up a company for manufacturing nuclear fuel, the bread and butter item in Mr Wedgwood Benn's proposals for the Atomic Energy Authority. It may be too soon to be sure that this proposal will survive under the new government, but it has every promise of doing so. By common consent, there is no reason why the government should continue to finance with public money operations which can be controlled easily enough by routine legislation, and financed, in part at least, by private capital. If Mr Wedgwood Benn was in his time in favour of an element of denationalization in this field, who will expect Mr Davies to hang back? The real difficulties are those not merely of the remainder of the Atomic Energy Authority, with its development organizations and research establishments, but of the other government research establishments concerned with aeronautics, electronics and a miscellany of vaguely scientific activities accounting for the best part of a third of the whole of British expenditure on research and development. What is to be done about them?

Mr Davies should perhaps acknowledge that it is mistaken to contemplate the entire disbandment of the Atomic Energy Authority, and, since the mistake is

the responsibility of Mr Wedgwood Benn, it should be comparatively easy for him to do so. It is not sensible for the British government to relinquish a direct executive control on the conduct of research programmes in fast reactor technology, and there is no assurance that the arrangements made with the private consortia will be an adequate substitute. To be sure, if all goes well in fast reactor technology, it may turn out that the two estimable groups of companies now in the business will be able to construct the reactors which the Central Electricity Generating Board needs and will also be well placed to export copies of them. But if the course of developments goes badly, everybody will be in trouble and the government will find itself wishing that there were some means of stoking the fires. In other words, there is a chance that it will regret any outright abandonment of an autonomous research programme and that, if it does now entirely wash its hands of research and development in this important field, it may have to start all over again in the late seventies. What this implies is that the plans for the reorganization of the Atomic Energy Authority which may be hatched in the weeks ahead should leave some room for a substantial programme of research and development. £10 million a year, or a quarter of the net cost of the Atomic Energy Authority in round numbers, should just about meet the bill. Elsewhere among the government establishments, it will be widely acknowledged that Mr Davies has a serious problem. Few ministers would be able to sustain in the Cabinet a fresh claim on a share of the national resources as substantial as that now given over to the research establishments. Cost benefit analysis would be brought to bear, and it would turn out to be hard to justify the cost. But the government is also committed, morally and in some cases contractually, to the people employed in the government establishments. Moreover, there are brave experiments such as those at Harwell where it begins to seem as if a government establishment may yet be a spring-board for independent enterprise. (The biggest snag is that if Dr Walter Marshall is as successful as his backers hope, he is bound to be snatched away to other, less productive jobs.) The problem, in short, is how simultaneously to diminish the government's direct involvement in research and development, to increase the incentive which government expenditure can provide for industry to improve its techniques and at the same time to remain not merely just but generous to those who have individually signed on for a career in science at a government establishment.

Mr Davies should recognize that no solution is

possible without a better market for scientists and technologists. If these were normal times, he might calculate that the natural erosion of the labour force at Harwell and places like that would ensure that the last part of his problem went away. As things are, while industry is less able than it should be to employ skilled people, some method will have to be found for bridging the gap. What is to be done? Is there a case for seconding people without charge to industrial companies? Most probably the most serious argument against that is the antipathy which has grown up in the past few years between the young men from the business schools (or those who wish they had been to business schools) and the old men of the sixties and even the fifties who believe that good engineering is an end in itself. Yet in numerical terms, the supply of skilled people is all too small, and it also turns out that those who have not been to business schools have nevertheless earned their money by programming computers or dealing less articulately

than the younger people with the concept of what the business schools call a system. In short, one of the government's chief duties should be to recreate the sense that the vast reservoir of skilled people in the government establishments can help to solve a lot of problems, some of them economic and some of them social. It is true that talk of white-hot technological revolutions is unfashionable (but Mr Wilson might still have been in office if he had listened more carefully to what he said), but there must surely be some programme rather than a form of words to which even Mr Davies could set his hand. In practice, he would have to be prepared to spend more money on enabling industry to employ scientists than is at present spent on the same function in the establishments. So urgent is the need that the precise way in which the money is spent is less important than that it should quickly become available as a carrot that will tempt the civil servants away from the establishments that have outgrown their functions.

Whom Does the Science Adviser Advise?

THE discussion last week about the role of the President's Science Adviser in modern American government seems to have been timely, perceptive and polite. The first thing to be said is that the office is highly individual. Like other high officials of the Administration in Washington, the Science Adviser is not so much a policy maker as a courtier. Such influence as he may have will often be seen to rest on his personal influence with the President, and the more influential he is, the more fondly he is regarded by the scientific community. If all goes well—but this is exceptional—the Science Adviser even becomes at once the idol of his President and of professional scientists, and the time then comes, no doubt, when he begins to ask himself whether he should not also run for the highest office. But when things go badly, the boot is on the other foot. The President has no time for the advice he has to tender and the scientific community regards him as the cause and not merely the instrument of its own sense of isolation. In other words, being Science Adviser is a job whose rewards would be appealing only to very few people and whose discontents would drive saints to despair.

The fact that Dr Lee DuBridge has come in for round criticism of his handling of this office is not explicitly his fault. This seems to have been what Dr James Killian and his colleagues were saying last week. At the same time, it is only right to acknowledge that in a highly personalized job like this, the personal attributes of the Science Adviser—though not his virtues—should be called up for examination. Film stars are, after all, sometimes sacked from coveted parts because their flair is for playing some other part. And company presidents are constantly being told by shareholders that they have lost their touch. It is

therefore not to be regarded as in any sense remarkable that a scholar of the highest distinction and a scientist of the most widely acknowledged reputation should not at the same time be one of those adroit but bullying politicians whose survival is likely to be most certain in the present climate in Washington.

If Dr DuBridge has been less powerful than he might have been for lack of the qualities that have earned courtiers a bad name, it is also only fair to say that times have changed, so as to have transformed the role of the Office of Science and Technology. In the statements of Drs Killian and Wiesner last week, there seems to have been more than a thin streak of sentiment. Both of them, after all, were looking back on periods when a courtier's life was relatively successful—and even so they may have frequently glossed over some of their disappointments. As things have become in Washington, what the Administration needs is not so much a Science Adviser in the sense that Killian first devised but, rather, a hard-headed but experienced man who can knock together the heads of the heads of the agencies whenever necessary. This is the task which the Science Adviser at present carries out in his role as chairman of the Federal Council on Science and Technology. But Washington also needs a device for making sure that the opinions of scientists can be canalized effectively towards some central point. In the past, the Science Adviser, by being chairman of the President's Science Advisory Council, has been able to do this job effectively. When the President has both a need and a liking for what his courtiers have to say, PSAC is a venerable institution. Now, with all the tensions that abound and with the growth of the profession of science, it would be much easier if the focus of the

scientific community's interest in the government could be elsewhere, chiefly at the National Science Foundation with informal links with the Pentagon and the other agencies. So long as there persists this conflict between the role of the Science Adviser as courtier and as lightning conductor, criticism of him and his office will persist. This is the point on which the congressional enquiries should concentrate.

100 Years Ago

Dictionary of Scientific Terms. By P. Austin Nuttall, LL.D., editor of "The Classical and Archaeological Dictionary," "Standard Pronouncing Dictionary," and numerous Educational Works. (London: Strahan and Co., 1869.)

WE are thankful to be able to say that we know nothing more of Dr. Nuttall than we learn from his title-page. We never even heard of him till we read his book, and we most sincerely hope that, as an author of scientific works, we shall know him no more. What the "numerous educational works" that he has published are we cannot tell, but if they are at all like his "Dictionary of Scientific Terms," the sooner they are consigned to the trunk maker and the butter-man, the better will it be for the welfare of the unhappy youths for whose benefit they were composed. These may seem hard words to apply to a writer who hopes to "receive every indulgence from a generous public" (p. xi.); but when that writer outrages all our better feelings by stringing together a series of idiotic absurdities, and calling the result a "Dictionary of Scientific Terms," how are we honestly to deal with him, except by exposing a few of his blunders? We will begin by testing his chemical knowledge. It will hardly be believed that he regards black-lead, brass, magnet, ochre, pewter, and steel as constituting "a few of the principal metals" (p. xviii.); that nitrogen is "unrespirable" (p. 230), although he has previously told us at p. 12 that it forms about 80 parts of atmospheric air; that oxygen "generates acids" (p. 239); that alum is "an earthy chalk, a sulphate of alumina or of potash" (p. 18); and that "culinary, rock, or sea salt, is chloride of soda" (p. 277). His natural history is as peculiar as his chemistry. We will merely put his zoology to the test, assuring our readers that in so far as accuracy is concerned, his zoology, botany, and mineralogy are much on a par. "Zoology," he tells us, "embraces an account of all animal creation, the principal classes being the *Mammalia*, *Aves*, *Reptilia*, *Pisces*, *Invertebrata*, and *Insects*." The first class is subdivided into nine orders, of which one is "*Edentata*, or animals wanting some of the teeth of other animals" (p. xiii.) Being anxious to learn more of these covetous, commandment-breaking creatures, we turned to *Edentates*, and found that they are "an extensive order of the class *Mammalia*, comprehending those unguiculated quadrupeds which have no front teeth, and divided into three tribes, the *Tardigrada*, the ordinary *Edentata*, and the *Monotremata*." We leave our zoological readers to decide how far this description is an accurate definition of the order, according to recent views, such as our author might have learned by consulting the works of Owen, or of Huxley.

From *Nature*, 2, 333, August 22, 1870.

OLD WORLD

ROCKETRY

Britain's Space Gold

A GOLD-PLATED sphere 76 cm in diameter will be the first satellite to be launched by a British rocket, as distinct from satellites launched for British scientists by the United States. With the usual proviso that all goes well, the satellite will be orbited on September 1 from Woomera. Together with the 13 kg satellite, equipment weighing 69 kg to check the performance of the rocket and the spent third stage of the rocket itself (42 kg) will go into orbit.

The three-stage Black Arrow rocket is a direct descendant of the Black Knight test rocket and it had its first firing in June last year. That was only a partial success, but it was repeated in March this year, when the rocket passed its test with flying colours. Next month's firing will therefore be the first orbital attempt—it was postponed from 1969 because of the initial failure.

Roughly equivalent to the American Scout rocket in that it will be able to handle payloads up to about 150 kg, the first and second stages of the Black Arrow burn hydrogen peroxide and kerosene, and the third stage has a solid propellant.

Although the first satellite, to be known as Orba, is diminutive as satellites go nowadays (China's first satellite weighed 380 kg, although Japan has orbited a 25 kg satellite) it apparently fills something of a gap in the scientific hardware in space that has already been noticed by COSPAR. The fine finish of Orba and its elliptical polar orbit make it ideal as a probe for measuring air densities and for observations of the motion of the upper atmosphere. Mr Desmond King-Hele and his colleagues at the Royal Aircraft Establishment, Farnborough, were the first to discover from observations of satellite orbits that the upper atmosphere must on average be rotating faster than the Earth. In fact the speed of the atmosphere varies from 1.4 times that of the Earth at heights of 400 km down to 1.1 times the Earth's speed at 200 km, and seems to have been detected at lower heights still (see for example D. G. King-Hele, *Nature*, 226, 439; 1970). Thus there is a dominant west to east wind at high altitudes that will be acting nearly at right angles to the plane of the orbit of Orba. (The orbit will be inclined at 82° to the equator.) The perigee and apogee heights, 350 km and 1,100 km respectively, make the orbit a compromise between a low orbit that would be strongly influenced by the rotation of the atmosphere but would lead to rapid re-entry, and a higher orbit for which the effect of the atmosphere will be smaller. The Farnborough group will be using optical and radio measurements of the change in inclination of the orbit to add to what is known about the rotation.

Between now and 1973, two or possibly three more launchings in the Black Arrow series of satellites are expected. The second satellite in the series planned for next year will be chiefly a technological satellite to test such things as an altitude control system, solar cells and new surface finishes, but it will also include a micrometeoroid experiment from the University of Birmingham. The third satellite, in 1973, will carry meteorological sensors, and it is said that there may be an additional satellite fitted in during 1972.

OPEN UNIVERSITY

Probation plus Costs

by our Education Correspondent

LAST week's announcement that the government is prepared to let the Open University enrol 25,000 students for next year does not signal an end to the university's fears for its future. But it does mean that the Open University will have a good chance to prove its worth before a final decision is reached by the Department of Education and Science. What the announcement made clear is that the university will be given a grant-in-aid to go ahead with its present plans, but that the government will discuss with the university authorities "the future scale of its operations, the contribution that it can make to the development of higher education provision in the future, and the prospects of increasing its revenue with a view to limiting the level of financial support from public funds". In other words, the university is on probation, and even if it comes up to expectations, it may have to take more of the financial burden on its own shoulders.

The cost to the Exchequer of running the Open University has not yet been worked out, but an early estimate suggested that the minimum basic costs—buildings, administration and so on—would be about £4 million each year. It now seems that the government has realized that the savings it is looking for will not be made simply by limiting the university's intake—for one thing, the chief costs are broadcasting time, tutoring and central administration, all of which are relatively insensitive to changes in student numbers—and it has therefore decided to see whether the university can at least pay some of its own way.

The university itself is not unduly alarmed by such suggestions, and it has already started to explore ways to take advantage of its unique position. The most promising source of finance is its own software, and the university authorities claim to have received expressions of "very high interest" from foreign universities and governments for the television and audio tape recordings of its foundation lecture broadcasts. There is also the possibility of selling books of correspondence teaching material—more than 100 have already been produced—but perhaps the most promising money spinner is the so-called MacArthur microscope which has been developed for the foundation course in science. The microscope packs into a small case, is powerful enough to cope with all the requirements of an undergraduate course, and will probably sell for about £10–£15. More than 8,000 microscopes will be required next year by Open University students alone, and the university's solicitors are at present trying to get patent rights on the instrument.

Other possible sources of finance are endowments and course fees, but the university is anxious not to raise its charges, because it does not want to discourage potential students. Even with the fees set at £140 for a BA degree and £180 for a BA with honours, the university succeeded in attracting chiefly middle-class students, while applications from manual workers and technicians were few and far between. The university will now be hoping for a wider cross-section of applicants for 1972 and for a drop-out rate of less

than 50 per cent, so that it can convince the government that it has an important contribution to make to the provision of higher education in Britain.

RABIES

Reprieve for Pets in Sight

IN recommending that dogs and cats should once again be allowed into Britain, provided that they are held in quarantine for six months and given at least two shots of anti-rabies vaccine, the committee of inquiry on rabies has settled for something slightly less than absolute safety. Whatever the merits of the complete ban on imports imposed last March, even that measure could not rule out smuggling by people loath to part with their pets, and in its interim report (HMSO, London, 1s 9d) the committee has decided that the small risks of controlled importing are preferable to the dangers of an untraceable source of the disease should a rabid animal enter the country illegally. But the ban will continue for other feline and canine species until the committee has made up its mind about the kinds of precaution that would be needed.

British quarantine regulations have already changed twice in less than a year. Last December, the length of quarantine was increased from six to eight months, following the case of a rabid dog which bit several people in Camberley soon after coming out of kennels, and the final ban was prompted by a dog which died of rabies at Newmarket nine months after arriving in Britain. At that time it was argued that six or eight months' quarantine was not safe enough, that longer periods were impractical because there was insufficient room in kennels, and that vaccination was too unreliable to be used instead. The combination of measures that the committee would like to see is strong enough to overcome all these arguments. Only inactivated vaccines would be used, and each batch would be rigorously tested for potency; animals would be vaccinated as soon as they arrived at their kennels, and again one month later; and records would be kept for nine months after release of where each animal was living. The committee has made a few preliminary suggestions for improving the isolation of animals inside kennels, but it will explore this question more fully—together with the precautions that should be taken if an outbreak of rabies occurred in the wild—in its final report.

Several myths about rabies seem to have been demolished by the scientific evidence that the committee has heard. There are no signs of the "important new strain" of rabies virus that the popular press was fond of earlier in the year, and neither is there any indication that the incubation period is tending to grow longer. On the other hand, the possibility that the virus might be transmitted indirectly, without a bite, from one animal to another within a kennel is still not ruled out. It is now, however, up to the Minister of Agriculture, Mr James Prior, to decide whether he thinks that the recommendations of the committee are strong enough to keep the enzootic rabies of Europe on the other side of the English Channel; and it will presumably be up to future Ministers of Transport to satisfy themselves that any tunnel under the Channel would be impenetrable to foxes.

CHOLERA EPIDEMIC

Tip of the Iceberg shows

THE cholera epidemic in the south of the Soviet Union, which seems seriously to have interfered with holiday traffic around the Black Sea, and which is being treated with great solemnity by the public health authorities in the Soviet Union, is by no means unexpected. Since the early sixties, it has been plain that endemic cholera has been spreading through India, Pakistan, South-East Asia and the Soviet Union. Although the number of known cases of cholera fell from more than 100,000 a year in the late fifties to less than 50,000 in 1960, the outward spread of the El Tor organism from Celebes in 1960 seems to have marked the beginning of what the World Health Organization has called the seventh epidemic of cholera (the sixth supposedly having lasted for the first quarter of this century). The countries first affected were those of South-East Asia and the region around the Himalayas, north and south, but even Japan has been affected on two occasions in the past decade.

Progress in the treatment and prevention of cholera, while steady, remains slow. With good diagnosis and facilities, the death rate of infected persons can be reduced from 60 per cent to 1 or 2 per cent, while there has been heartening if predictable progress in the treatment of various complications such as those of the liver. One of the difficulties in the prevention of the disease has been the comparatively short duration of the immunity conferred by the vaccines developed in the past few years. For one thing, vaccination seems to be effective only in roughly half of those treated and its effects persist only for six months or thereabouts. An expensive series of controlled field trials sponsored by the World Health Organization in the past six years has so far yielded no spectacular improvement of vaccine prophylaxis. Much work remains to be done on the identification of cholera carriers in the population, while the epidemiology of the disease and the incidence of immunity in populations in which cholera is endemic requires attention only now being devoted to it.

ATOMIC ENERGY

Rising Budget for IAEA

THE doldrums appear to be over for the International Atomic Energy Agency in Vienna, which is now counting on having \$13.78 million to spend in 1971, an increase of 10.1 per cent on the year. The agency's work for the safeguarding of nuclear power installations, and its planning for the time (two years ahead) when the Non-Proliferation Treaty will have to be policed, account for much of the increase. In 1971, safeguards procedures will indeed take 11 per cent of the total budget, at least if this is approved when submitted to the board of governors of the agency in September.

Elsewhere in the pattern of the agency's spending, the outlook is not as cheerful. The technical assistance programme, on which a great many underdeveloped countries have relied and to which many others look for technical help with the development of nuclear industries, will have an extra \$16,000 or just over 2 per cent more to spend next year. Much the same is true

of the other items in the proposed budget—the Centre for Theoretical Physics at Trieste, for example, will have to look for any increases of expenditure to other organizations than the agency.

One striking feature of the budget document now circulating is the forecast which it includes of expenditure in the period 1971–76.

ANTARCTIC

Russia moves West

by Our Soviet Correspondent

THE latest projected Soviet research station in the Antarctic—the Leningradskaya—represents a new venture in the Russian exploration of the continent. For the first time, a Soviet expedition will be operating in the western area, on Ots Bay, outside their traditional eastern sector. This change, according to the deputy head of the Soviet Antarctic Expedition, V. M. Rogachev, is part of a programme to obtain more complete data about the whole Antarctic continent, and it will be followed by the establishment of a further, as yet unnamed, “bridgehead” on Cape Dart. Russia will then have a series of seven research stations, spaced at approximately equal intervals around the periphery of the continent.

An advance party of six, headed by the distinguished polar scholar, A. B. Budretskii, will travel out to the Leningradskaya site, as part of the sixteenth Soviet Antarctic Expedition, preparations for which are now well under way. This expedition, which will comprise in all some 300 persons, is to undertake a comprehensive programme of research, including a continuation of the series of deep bores into the ice-cap, already successfully initiated by previous expeditions.

PHYSICS

Following in Weber's Footsteps

Two groups in England are among those preparing to test Professor Joseph Weber's claim to have detected gravitational radiation. Neither Mr P. Aplin at the University of Bristol nor Professor W. D. Allen's group at the Department of Applied Physical Sciences at the University of Reading seems dismayed that Professor Weber's work has not been without its critics, and that the astronomers are hard pressed to account for the huge flux of gravitational radiation that his experiments, taken at face value, have detected. Both take the view that Professor Weber's work needs to be independently tested.

Professor Allen and Mr Aplin both began thinking seriously about setting up detectors for gravitational radiation in June last year. Mr Aplin expects to have his working within a few months, but Professor Allen's may take a little longer. Both pieces of equipment are roughly along the lines of that used by Professor Weber at the University of Maryland, and at the Argonne National Laboratory, and they will both be tuned to the same frequency, 1,661 Hz. In the first instance Mr Aplin and Professor Allen will be looking for coincidences between the signals picked up by their detectors—later they hope to cooperate with Professor Weber and other groups to establish a world-wide net to catch gravitational waves. Both have financial support from the Science Research Council and from their own universities.

Chips off the Plates

THE twelfth leg of the zigzag voyage of the deep-sea drilling vessel *Glomar Challenger* around the oceans of the world "achieved more than I ever expected", Dr Anthony S. Laughton of the National Institute of Oceanography, Surrey, said in London last week. Dr Laughton, who was co-chief scientist with Dr William A. Berggren of Woods Hole Oceanographic Institution, Massachusetts, for the fifty-five day cruise which ended in Lisbon on August 11, was presenting the first scientific reaction to the three thousand feet of cores that were collected. Leaving Boston on June 17, the ship described an arc up to 60° north that took in thirteen drilling sites at the edge of the continental shelf off Newfoundland in the Labrador Sea, on the Reykjanes Ridge south of Iceland, the Rockall Plateau and in the Bay of Biscay.

This latest cruise of the *Glomar Challenger* is the first with a co-chief scientist from outside the United States, reflecting the growing internationalization of the programme. The trend continues on the next leg, which is covering the Mediterranean and which ends at Lisbon on October 6. Cruises have been mapped out until August 1972 when the additional support for the programme that the National Science Foundation awarded last year comes to an end. Following the exploration of the Mediterranean, the *Glomar Challenger* will take a more southerly route across the Atlantic to Puerto Rico for investigations in the Caribbean, and will then follow a devious circumnavigation taking in areas of geophysical interest in the northern Pacific, the Indian Ocean, and the south Atlantic.

The drilling vessel *Glomar Challenger*.

Although Dr Laughton was speaking only days after the conclusion of leg twelve, he was able to report several notable achievements of the cruise. From the technical point of view it had been pleasing that deep-sea drilling had proved feasible up to 60° N in the north Atlantic. Only half a day's drilling out of fifty-two had been lost because of the weather. Using

techniques developed for the ill-fated Project Mohole, the *Glomar Challenger* stays within a circle of a 100-foot diameter for the several days that it takes to complete a drilling.

Scientifically, the cruise has collected cores from several fragments of continental material left behind by the opening of the north Atlantic, has shown that the Gulf Stream once flowed into the Labrador Sea, and unexpectedly has revised the date of the commencement of the last glaciation. The continental fragments are evidence that the break between North America and Europe was not as clean as that producing the jigsaw fit between Africa and South America. Greenland was also left behind, but Iceland is a purely volcanic island built up from the mid-Atlantic ridge. To begin with, cores were recovered from Orphan Knoll, an isolated seamount just beyond the continental shelf near Newfoundland, and the deepest core recovered was a black sandstone containing fragments of anthracite that might have been laid down in a river bed, showing that the seamount was once a low-lying continental fragment. The same kind of evidence was unearthed from the Rockall Plateau, and Drs Laughton and Berggren say that they have enough data from two boreholes to give a chronological history of the sinking of the plateau after it separated from Greenland 56 million years ago. But why these two regions should be disappearing into the seabed—at a rate of one foot every thousand years for the Rockall Plateau during the last of the three stages of sinking that have been identified—is still a mystery.

Two boreholes in the Labrador Sea contained layers of rock fragments, at a depth corresponding to 3 million years ago, that are believed to have rained down on the seabed from melting icebergs. Dr Laughton said that this is an earlier date than previously thought for the beginning of the last glaciation in the North Atlantic. It corresponds to the middle of the Pliocene, and is the first strong evidence that the glaciation was earlier than the boundary between the Pliocene and the Pleistocene, 1.8 million years ago. Beneath the glacial debris, the cores contain subtropical organisms showing that before the glaciation the Gulf Stream was probably flowing along the Labrador coast.

The drillings on the flanks of the Reykjanes Ridge have demonstrated that the thick sediments there are due to turbidity currents depositing large amounts of material and do not have to be interpreted by variations in the rate of seafloor spreading. In the Bay of Biscay the intention was to find how long ago the bay opened due to the rotation of Iberia away from France, but so far the data from two boreholes are inconclusive.

In the Mediterranean, the scientific crew of *Glomar Challenger* will be collecting cores from a closing sea to compare with those from the Atlantic. The co-chief scientists, Dr Kenneth J. Hsu of the Swiss Federal

Proposed boreholes in the Mediterranean.

Institute of Technology in Zurich and Dr William B. F. Ryan of the Lamont-Doherty Geological Observatory, will be investigating the formation of Sardinia, Corsica and the Italian peninsula, and looking for evidence that the eastern Mediterranean was once a large sea that has been crushed as a result of the spreading of the Atlantic and Indian Oceans.

But, at present, drilling is hampered by what the members of the crew call the "chert barrier"—layers of chert, a rock similar to flint, that have turned out to be unexpectedly abundant beneath the seabed. The chert blunts the drill bit surprisingly quickly, and when that happens drilling in that particular borehole has to finish. Once the dulled bit has been retracted there is no way in which the entrance to the borehole can be found again. This is why the permanent members of the deep-sea drilling project are still rejoicing over a test carried out off New York just before leg twelve in which it was proved that when the *Glomar Challenger* is equipped with a high resolution sonar the drill can be guided into an old borehole if the borehole is capped with a metal cone 16 feet in diameter to direct the drill. This technique will be used in earnest for the first time on leg fifteen in the Caribbean when the ability to replace worn bits will allow deeper drilling than before. During leg twelve the deepest core came from 3,000 feet below the sea floor, and drilling was conducted in water depths up to 16,000 feet.

Can the IAU hold its Head above Water?

from our Special Correspondent

Brighton, August 18

It will be interesting to see if the fourteenth General Assembly of the International Astronomical Union, now in session here, can avoid being swamped by its participants. 1,800 astronomers, representing all branches of their discipline, and their 500 guests have descended on Brighton for the assembly, which takes place every three years. The choice of this part of southern England is recognition of how astronomy has blossomed here, at the nine year old University of Sussex and at the Royal Observatory close by near Eastbourne. On Monday evening during the registration formalities which everybody had to go through, there were signs of chaos, in spite of the computer printouts of participants' names that were being used. Perhaps that was to be expected at the start of a conference of this size—people were saying that Prague was worse three years ago.

Nevertheless, nearly everybody in astronomy is here, and on this basis the assembly cannot fail to be remembered as a success. All the same, old astronomers may lament the day when a general assembly of the IAU really was something. Then people might travel for days or even weeks on a boat for a rare chance to talk with other people in their subject. For a great many astronomers, international conferences are two a penny nowadays. That is why one of the resolutions to be introduced at the opening assembly was that, after 1973, general assemblies should be at four year intervals. It still holds true, however, that astronomers working at small remote observatories which tend to be cut off from the mainstream abroad probably value assemblies more.

That is one of the reasons why the discussions of the forty or so commissions into which the IAU has divided astronomy—the main business of the general

assembly—are so important. Before the assembly, the president of each commission writes a draft report of what has been happening in that particular subject during the past three years. These draft reports, which are polished into a final version by discussion at the commission's meetings, can be very good—the best are read by astronomers wanting to brush up their knowledge of a particular field. Much depends on the character of the president, however, and some allow their meetings to degenerate into a discussion of what is to be discussed. "Sitting there, filling their waistcoats", is how one astronomer described it, lamenting the preoccupation with organizational problems at some of the commissions.

Even if a general assembly is less interesting than the small congresses on specialist topics that the IAU is organizing all the time, the IAU as a body is of inestimable value to astronomy. It smoothes a way for the international exchange of astronomers that would otherwise be fraught with political difficulties. It is responsible for the telegraph service that informs astronomers around the world of important news—the discovery of supernovae, new pulsars, comets and the like. It concerns itself with the protection of radio astronomy bands from interference. Most important is the work the IAU does for international collaboration, vital for such studies as long baseline interferometry and source surveys.

A nice question with political overtones has blown up about where the 1973 assembly is to be held. The Russians suggest Warsaw to coincide with the 500th anniversary of the birth of Copernicus in Poland, but the Australians want Sydney. The problem is that by IAU rules the invitation has to come from the host country, and Poland so far has not indicated what it wants.

NEW WORLD

Grumbles at Dr DuBridge

THE Office of Science and Technology and the role of its chairman, the President's Science Adviser, have once again commanded the attention of the House Subcommittee on Science, Research and Development, which is conducting hearings on the matter of whether the United States should pursue a national science policy, whatever that may be. Two former science advisers who appeared before the committee last week, Dr James R. Killian and Dr Jerome Wiesner, defended by implication the present incumbent of the office, Dr Lee DuBridge, who has been accused of failing to protect the interests of the scientific community. Other witnesses, however, had harsh words for Dr DuBridge and his office.

Dr Edward U. Condon, for example, professor of physics at the University of Colorado, bluntly referred to the "dwindling influence" of the President's Science Adviser and to the fact that three months ago, when major changes in the White House staff were announced "the Science Adviser and his Office of Science and Technology were not shown at all in the organization chart as published in the *New York Times*". Failure even to mention the office indicated to Dr Condon that "the President is unaware of the importance of science in the world today. This strikes us all the more forcefully in the light of experience in the past 18 months, in which partisan political considerations seemed to dictate choice of individuals for major appointments in government science agencies". Dr Condon may have been thinking of the case of Dr F. Long, whose nomination as director of the National Science Foundation fell through when his attitude towards the antiballistic missile system became known to the President. The general theme, if not this specific instance, was certainly on Dr Condon's mind, for later in his testimony he warned that "many scientists feel that there are now signs again of renewed repressive tendencies like those which were so strong in the 1952-60 period".

Dr Condon's disappointment in the Office of Science and Technology was shared by Dr Raymond Bowers, professor of physics at Cornell University, who told the committee that in the past few years the office "has not played the strong role that is necessary if we are to introduce better management into the federal science enterprise". Dr James Killian, too, remarked that although the Office of Science and Technology has sought to moderate cutbacks, "the fact remains that an accumulation of uncoordinated actions has brought disorder and dismay in the house of science". But both Dr Killian and Dr Wiesner made clear that the loyalties of a president's Science Adviser are to the President and not the scientific community. Asked if he saw any need for a reorganization of the Office of Science and Technology, Dr Wiesner explained that because of the size and complexity of the Cabinet offices, "cabinet officers become more advocates of their agencies, no matter how hard they try not to, than impartial agents of the President, so the President

finds himself a captive of these organizations. The most important problems of the President's Science Adviser and the President's Science Advisory Committee are to act as assistants and see that the President has had a full range of advice". Dr Wiesner added that there were those who thought his job should have been to represent the scientific community to the United States Government; "I felt my role was to ensure the healthiest possible scientific activity for the country's technological efforts, but this is very different from being spokesman for the scientific community".

Dr Killian agreed that the mechanism for advising the President on scientific affairs "ought to be built to serve the President in a way that is not caught up in the interdepartmental advocacy . . . and to give objective advice that is unrelated to the partisan interests of given departments".

Several witnesses have dwelt on the plight of graduate education and their number was added to by Dr Wiesner, who wanted to see the responsibility for higher education separated from the lower kinds and embodied in a National Institute of Education, which might become part of the National Science Foundation. Dr Bowers hailed as the great need of the next decade "the construction of a more rational and comprehensive system of support for graduate education in its own right and the moving away from a situation where graduate education is largely subsidized as a beneficiary of research support". Dr Bowers, too, believed that the National Science Foundation was best suited to administer the support of graduate education in the sciences.

Other reorganization plans pressed on the committee included Dr Condon's proposal that Congress should set up a Joint Committee on Science Policy which would oversee the relationship between science and other fields such as the health services and the elimination of war. Another joint committee, to be called the Joint Committee on Science and Technology, was proposed by Mr Pat Haggerty, the chairman of Texas Instruments, who envisaged such a committee as being the Congressional counterpart to a stronger Office of Science and Technology. Mr Haggerty believed that the present office does a creditable job considering that it has only twenty professional staff, but in a better world the office would be folded into a much larger Council of Science and Technology Advisers, similar to the Council of Economic Advisers.

It was Mr Haggerty who made perhaps the cleverest speech (though not necessarily the most illuminating) that the committee has yet been treated to. Not for him the ritual wringing of hands at the golden age that is no more. He launched his audience straight into an economic analysis which revealed that the United States has a favourable trade balance in only one of four kinds of product, those that are "technology intensive". But in this crucial sector the country's trade with its two chief competitors, Western Europe

Why Science is in a Mess

"FEDERAL reductions and shifts in science support appear to have been taken without the integrative guidelines of a policy consensus. Each of these actions might have seemed reasonable within the narrow context in which it was decided, but they are now having a cumulative effect which threatens to be very damaging not only to American science but to our universities. Taken together, these actions may curtail the amount and quality of basic research. They may diminish our capacity to educate scientists and engineers. They threaten to discourage young people from electing science and engineering as fields of study. They threaten the breakup of experienced teams of talented scientists and the closing of facilities. They threaten to erode the pre-eminent position of the United States in science and technology. They provide a telling example of the need for new policies which can help to reduce uncoordinated federal decisions.

"These federal actions include Section 203 of the Military Procurement Authorization Act for 1970 [otherwise known as the Mansfield amendment which prevents the Department of Defense from supporting basic research not obviously relevant to its needs]; abrupt changes in federal student aid programmes, such as the cutback in the National Science Foundation's traineeships; the reduction of the National Defense Education Act graduate fellowships and those of the National Institutes of Health which may be phased out; the phasing out of the NASA traineeship programme and the sustaining university programme without replacing them by other programmes to prevent rocking the boat; the expenditure ceilings imposed on the National Science Foundation; NIH's negotiated reductions in grants; the possible curtailment of funds for the national defence student loan programme; and the Administration's proposal for a family income ceiling of \$10,000, above which students could no longer receive interest subsidies (despite high continuing interest rates) for guaranteed loans.

"It is exceedingly important to look at the additive effect of all of these actions, some initiated by Congress and some by the Executive Branch. The total impact of these independent, unrelated actions is not only affecting the high level of funding available, but it is introducing a high degree of instability and uncertainty in the conduct of basic research and in its fiscal planning; and there is in addition an adverse financial impact on the entire university. It is eroding the carefully nurtured partnership of the Federal Government and our universities which has been so spectacularly successful over the thirty years."—Statement by Dr James R. Killian to the House Subcommittee on Science, Research and Development on August 11, 1970.

and Japan, declined from a favourable balance of \$1,600 million in 1962 to only \$700 million in 1968. Based on present rates of growth in population and gross national product, Western Europe and Japan may attain a GNP per capita as large as or even greater than that of United States (\$8,500) by the year 2000.

"Need I say more?", Mr Haggerty could almost be heard to ask at this stage, but he went on to spell out his belief that further improvement in the national quality of life depended on improving the national competence in science and technology, whereas total research and development activity in the United States had in fact declined, from its highest ever level of \$25,400 million in 1967 to an estimated \$27,250 million in 1970. This may not look like a decline, but of course \$27,250 million received in 1970 is worth only \$23,250 million in the currency of 1968.

How much money should be devoted to science, academic and otherwise? Mr Haggerty thought that the recent decline in support was inevitable, granted the pressing nature of society's other needs, but the erosion of scientific research should not be allowed to proceed any further. An increase in the federal support for science of about 6 per cent a year would take account of inflation and even allow a little real growth to occur. Mr Haggerty thought that a reasonable increase of this nature should be guaranteed for the next three years or so, because of the long range nature of science and so as to avoid the kind of aberrations in support that underlie the present problems. Just what those aberrations are and the damage they have brought about, nobody has explained more succinctly than Dr Killian (see this page).

ABM

Boondoggle or Bargaining Chip?

from our Washington Correspondent

ONCE again the Senate has been bullied by the Administration into allowing the deployment of the Safeguard anti-ballistic missile system to proceed as planned. Last week, which marked the end of the second round of SALT talks at Vienna, the Senate rejected by a margin of five votes a proposal that would have restricted Safeguard to the two bases at which work has already begun. Unless a slightly milder version of the same proposal is passed this week, the Pentagon will be able to build Safeguards at two additional sites, making four in all.

Since last year's Senate debate, when Safeguard was saved by a single vote, the emphasis of the argument has shifted from whether or not the system will work to whether it will be a useful bargaining counter at the SALT talks. The government is sufficiently persuaded of the system's importance to have twisted the Senate's arm with a last minute telegram from Ambassador Gerald Smith, the United States negotiator at the SALT talks, implying that without the prospect of Safeguard being built the Russians might lose all interest in the arms talks. The telegram, whose contents have not been revealed, is said to have swung the debate against the proposed limitation of the Safeguard system. The views expressed in the telegram, whatever they may be, have aroused the

suspicions of Safeguard's opponents because in testimony before a Senate committee earlier this year, Ambassador Smith strongly implied that he had enough bargaining leverage without any extension of the Safeguard system.

What with the technical and diplomatic complexities of Safeguard, and with much of the relevant information unavailable, a natural inclination would be to give the government the benefit of the doubt and let it do what it thinks best. Any such confidence is tempered by the fact that the Pentagon planners seem to have changed their minds several times about what the system is supposed to do and how it is to do it. Yet while the task of Safeguard has changed, its hardware is still based on the Nike-Sentinel system which was rejected as inadequate when first proposed. It is little wonder that many independent scientists, including three of the four former science advisers to the President, have gone on record as opposing the system whether for its technical deficiencies or other reasons (see *Nature*, 226, 893; 1970). In last week's debate there emerged further signs of disenchantment with Safeguard among the scientific community, together with evidence that the Pentagon is beginning to share some of their scepticism, at least to the extent of devising a new version of the Safeguard system known as Project Hardsite.

The basic elements of the system, the fast Sprint and Spartan missiles, and the perimeter acquisition (PAR) and missile site (MSR) radars, were originally designed to defend cities against a light Chinese attack, although from quite early on there seems to have been the option of upgrading the defence to meet an attack on cities by the Russians. Early in 1969, however, the Sentinel system, as it was known, was rechristened Safeguard and sold to Congress as a means not only of defending people against the Chinese but also of defending Minuteman missiles against the Russians.

This position smacked of commonality, the concept by which Mr McNamara tried to thrust the disastrous F-111 aircraft down the throats of both the Navy and the Air Force, and last month the powerful Senate Armed Services Committee persuaded the Pentagon to drop the idea of building Safeguards to defend against a Chinese attack on cities and to concentrate instead on protecting missile sites. Meanwhile critics had begun to argue that the heart of the Safeguard system, the missile site radar (which together with its ancillary computers costs the best part of \$200 million), could easily be knocked out by Soviet SS-11 missiles (roughly the equivalent of Minuteman missiles), which would leave the 150 or so Minutemen under the MSR's protection defenceless against attacks by SS-9 missiles. In their present form SS-11s cannot knock out a Minuteman in its silo, but the giant SS-9 missiles, which the Russians began redeploying in June, are believed to carry three 5-megaton warheads whose re-entry pattern happens to coincide with the spacing of the Minuteman silos. Moreover, the Soviet Union has begun to equip its SS-11 missiles with multiple warheads (a test firing with two dummy warheads was reportedly made earlier this month), which would raise the number of Sprint interceptors required to defend the MSR.

These Soviet moves have been accompanied (some say caused) by the United States' decision to start deploying multiple warheads on its Minutemen as

from June and in its Poseidon submarine missiles from December this year. The effect on the ABM debate has been for the supporters of Safeguard to point out how badly it is needed and for the critics to claim that it would not work against this kind of opposition; moreover, since the Russians know this, Safeguard is useless even as a "bargaining chip" which might be dropped in return for the Russians cancelling their SS-9 programme. The point was most succinctly put in the Senate debate by Mr Young of Ohio who said, "The Nixon Administration has claimed the Safeguard is absolutely essential as a defence against the Chinese. How then can they justify trying to trade it away to the Russians? If it is an essential system, we should keep it; if, as appears to be the case, it is a worthless boondoggle, the Russians surely know it and there is nothing to be gained by deploying it for bargaining purposes. Safeguard is not the billion-dollar poker chip the administration claims it is."

Much of the disquiet about the system's capabilities has sprung from the O'Neill report, a study of Safeguard by independent scientists that was convened by Dr John Foster, the Pentagon's Director of Defense Research and Engineering. Members of the study group included Dr Marvin L. Goldberger, until recently chairman of the President's Science Advisory Panel on Strategic Weapons, Dr Sidney Drell, also a member of the panel, and Dr Lewis M. Branscomb, director of the National Bureau of Standards.

The burden of the group's report, which was delivered to Dr Foster and Secretary of Defense Melvin Laird in January but not made public until last week's debate, was that if the only purpose of Safeguard was to defend the Minuteman silos, the project should proceed no further. In its place a "dedicated" system should be developed which would have smaller and cheaper radars than the MSR, with each radar defending fewer silos. The Department of Defense had clearly reached a similar conclusion, because included in the \$1,027 million being sought from Congress for the second phase of the Safeguard (last year's bill for getting started on Safeguard was \$1,600 million) are requests for \$35 million for extra Sprint missiles which are now deemed necessary and for \$58 million for further design work on Project Hardsite.

Project Hardsite appears to be intended for just the purpose recommended by the O'Neill panel for Safeguard. It would defend fewer silos than the 150 protected by a Safeguard, each radar having a smaller range than the giant MSR and controlling fewer interceptors. The advantage of creating smaller units was explained to a House Subcommittee in April this year by Mr Richard L. Johnson, Assistant Secretary of the Army for Research and Development. He described how, by reducing the range of the system's radars, and hence the number of attacking missiles each can see, there are considerable savings in the size of the data processing problems involved. In other words, reducing the capability of the radar enhances its efficiency. Mr Johnson told the committee that the project was in the stage of "concept formulation", which meant deciding the optimum size of the radars and computers and showing analytically that it was a viable system. Dr Gilstein, head of the Pentagon's Advanced Ballistic Missile Defense Agency, added that the computers for Project Hardsite already

exist and the software is now being written. The technology for much of the radars also exists, through a complete radar has yet to be built. Asked about the likely cost of Project Hardsite (at the time of the committee's hearings Safeguard was being upheld as a way of protecting cities as well as missile sites), Mr Johnson said that it would be "less expensive than Safeguard to defend the Minuteman. If you are talking about the present amount for Safeguard it would be that or less."

What are the chances of either Safeguard or Hardsite being built? Proponents of the system, who have stressed its value as a bargaining chip, have put forward the comforting view that the Russians face a similar situation to that of the Americans, having a suspicious and obdurate military to deal with and even, it is implied, not so few bugs in the SS-9 that they wouldn't be as glad to ditch it as the United States would be to say farewell to Safeguard. One of the proposals announced at the end of the present SALT talks last week was in fact an American offer to limit Safeguard in exchange for a Soviet curb on the SS-9. The irony of the Cooper-Hart amendment which the Senate rejected is that in asking for a mere \$322 million reduction in the budget for Safeguard it would scarcely have diminished the credibility of the system or the present prospects for a trade-off against the SS-9. But it is little wonder that the Administration is as pleased as Punch with the defeat of the amendment. For if no bargain is struck the Administration will appear to have made a far sighted investment in a system vital for the nation's defence, and if Safeguard is traded away it will be Mr Nixon, not the Democrats in the Senate, who can claim credit for all the economies that will ensue upon its demise.

CYCLAMATES

FDA's Last Somersault

NEVER can an important agency of government have reversed on its stand so erratically or so frequently as has the Food and Drug Administration in the matter of cyclamates. In October last year, the Department of Health, Education and Welfare, on the FDA's advice, banned the artificial sweeteners in a manner that has served as the paradigm of how not to handle such matters. A month later the FDA partly reversed its stand by permitting some food and drinks containing cyclamates to be sold over the counter without prescription provided they were labelled as drugs. Last week the FDA reversed this decision too on the grounds that cyclamates are no longer effective as drugs.

It stretches the credulity near to its utmost limits that the "new information" on which the FDA has now acted became available in the form of an internal FDA memorandum dated November 26 last year, a bare seven days after the meeting at which the decision was taken to allow the sale of cyclamates as drugs. The memorandum, prepared by H. L. Richardson and colleagues, describes the feeding of cyclamates to rats for periods of about 100 weeks.

The basis of the new decision is the finding reported in the memorandum that the safe feeding level of cyclamates in rats is not 1,120 mg/kg a day, as appeared to be the case at the time of the original ban in October, but 240 mg/kg a day. Adjusting the dose downwards

to give the customary 100-fold safety factor, the assumed maximum safe daily dose of cyclamates is 2.4 mg/kg or 168 mg a day for a 70 kg adult. Since this is equivalent in sweetening power to only 5.1 g of sucrose or 21 calories, the benefit to a diabetic or weight-saver is negligible. Hence cyclamates are not effective as drugs, so that food products containing cyclamates will not be permitted to be marketed as such.

PSYCHOLOGY

Repeal of the Porn Laws

LORD CHESTERFIELD once remarked of sexual intercourse that "the pleasure is momentary, the position ridiculous and the expense damnable"; much the same set of emotions has been evoked in a congressional committee by the President's Commission on Obscenity and Pornography, which has had the misfortune to have a draft report of its findings leaked to the committee before being able to decide on its final recommendations. The research work performed for the commission (at a cost of some \$2 million over the past two years) indicates that the most harmful effect of exposing people to pornography, at least in a laboratory setting, is not so much a propensity to violent or deviant sexual behaviour as an insupportable boredom.

Other, perhaps less predictable conclusions of the draft report are that women no less than men may be excited by erotic films and pictures, that basic attitudes and patterns of sexual behaviour do not change after viewing pornographic films and, to give just an extra flutter to the red rag being waved before congressional noses, that the politically conservative are less easily aroused by pornography than those inclined to the left of the political spectrum. The draft recommendations—not yet accepted by the Commission—apparently call for laws that would be almost as liberal as those of Denmark, possibly the only country whose legal attitude to pornography is more tolerant than that of the United States.

The commission is expected to announce its findings on August 30 or later, but meanwhile the events occasioned by its draft report have taken a predictable turn. The Administration has been busily washing its hands of the Commission and all its doings, protesting that it was President Johnson who set up the Commission and appointed its members. And the House Subcommittee on Postal Operations, to which the draft report was leaked, has leapt in to quarrel with the Commission's conclusions and methodology. The committee's star witness last week was Dr Victor B. Cline, professor of psychology at the University of Utah, who in a statement to the commission in May had taken issue with the quip that "no girl was ever ruined by a book". "While this is slightly humorous, of course," Dr Cline admitted on that occasion, "we know this isn't really true. The Protestant Reformation was ignited by a written proclamation." No less firmly than Luther hammering his edict onto the church door at Wittenberg, Dr Cline banged the nails into what he hoped would be the Commission's coffin. He told the subcommittee that the report was "a gross mixture of truth and error, part science fiction and certainly a travesty as a scientific document attempting to do a judicious and fair survey of the literature in this area".

After reading the Commission's draft report (though without the original data) Dr Cline criticized its biased review of the literature, uncritical use of data and neglect of basic definitions. "To put it in a less charitable way, I doubt that any decent university psychology department would ever award a Master's thesis on the basis of such an incautious review of the literature as this is, and especially the unwarranted conclusions drawn from the data."

A hostile Congressional committee is not the cosiest forum before which to give the technical details of one's experiments their first public hearing, but this was the ordeal that faced two groups of psychologists who had undertaken research for the Commission. Dr Cline having prepared the way, it was the turn of Dr Sheldon Starr, of the Veterans Administration Hospital's Family Study Unit, to describe how he and his colleagues had investigated the effect of exposing married couples to pornography. Their subjects, all of whom had been married for at least ten years, were recruited from an advertisement in a Palo Alto newspaper (remarkably, 16 per cent of them had PhDs). The purpose of the study was to ascertain by questionnaires whether there was an alteration in the manner or frequency of the couples' conjugal relations after exposure to erotic films. The anticlimactic conclusion of the survey (which cost some \$20,000) was that "exposure to these films produced only a very brief and transitory increase in the subjects' sexual behaviour during the time the films were being shown. But in the period afterwards the level of sexual activity decreased."

Much the same tale was told by Dr James L. Howard, professor of psychiatry at the University of North Carolina. He and his colleagues exposed some 20 male students to pornographic materials for an hour and a half a day for three weeks, the subjects' response being monitored by a plethysmograph (an instrument for measuring small volume changes) and by assaying the quantity of acid phosphatase (an enzyme of the prostatic fluid) in urine samples. Although the subjects "thought more about sex" during the first few days of the experiment, there was no change in their previous patterns of sexual behaviour. To begin with, they spent about 90 per cent of their time looking at the pornography available for them but by the end of the experimental period only 35 per cent, and "there was a consistent downward trend all the way through the time course of the experiment".

Several of the subjects said they would refuse to participate in the experiment again because it was very dull, and Dr Howard thought the committee might be interested to know that "to a man they considered the question of the control of smut to be among the very minor social concerns of the day. Most of them found it difficult to think of a less important social issue."

ADDICTION

Programme on Heroin

from our New York Correspondent

IN an attempt to cut through the rhetoric and emotionalism that surround the heroin problem, Dr Gilbert Levin, an assistant professor of psychiatry at the Albert Einstein College of Medicine, has set a computer to work on the causes of heroin addiction in

a New York City neighbourhood. The study, supported by a \$100,000 grant from the National Institute of Mental Health, is meant to force administrators to think about the problem in logical rather than emotional terms. The computer model is constructed from a series of equations representing statements about the causes of developing problems in the area. The information has come from a variety of sources, including the police, addicts, parole officers, doctors and neighbourhood residents.

The area being studied contains approximately 180,000 people, most of them white. Dr Levin feels that the model will be applicable to a wide range of communities with a few alterations in the initial assumptions. "It would be reasonably easy to make the necessary changes except for the extremes—the very rich or the very poor," he said. With the help of Edward B. Roberts, a management professor at the Massachusetts Institute of Technology, and Gary Hirsch of Pugh-Roberts Inc., a Cambridge, Massachusetts, consulting firm, he has designed the systems analysis programme to provide a "time study" of how solutions applied to the problems would affect the situation over a 25 year period.

The study has not yet taken account of the British approach to legalized heroin although it intends to do so, but Dr Levin considers that in the United States, any extreme solution would have destructive short-run consequences. If the supply of heroin were suddenly increased through legalization, addicts could obtain heroin but the black market supply would have to find new users. This would lead to a selling drive among the young and the number of new addicts would increase. Equally, if the heroin supply were cut off suddenly, there would be an increase in crime as desperate addicts searched for enough money to buy the limited amount of heroin available. If either course were carried out more gradually, the results might be beneficial, Dr Levin said, but this could only be determined after more study.

The use of methadone, a synthetic drug that is addicting but is supposed to block both the effect of heroin and the addict's craving for it, allowing him to function normally, is on the increase in New York and throughout the country. It is not meant as a universal panacea, but too many communities see it as a simple solution to this complex problem. The computer suggests that if methadone alone were used, new addicts would be spawned faster than any methadone programme could handle them and that many younger addicts would reject it. Dr Levin is hopeful that methadone will prove a useful tool in combating addiction as long as it is not relied upon totally.

This is also true of the other stop-gap measures that have been tried in the past. The usual punitive approaches to addiction, treating it as a crime rather than the disease it is, have little if any effect in themselves. If the police alone are used to handle addicts, the computer predicted that the gaols and courts would be filled to overflowing with addicts and the neighbourhood would deteriorate, with middle-class families fleeing addict-related crime. "While the police are necessary to keep down drug availability within the community, thereby slowing the growth of addiction in the area, inroads into drug growth can only be made when the police are working simultaneously with other preventive approaches," Dr Levin said.

Potentially, education is one of the most effective ways to combat the growth of drug addiction, but no one is yet sure what programmes are really effective in reaching the young. Dr Levin makes the distinction between "credible" and "incredible" education. Incredible education includes some statements or attitudes that are false or exaggerated; such programmes have zero or negative effectiveness since all the information, both false and true, is rejected as untrustworthy. But if education can be credible, Dr Levin is hopeful that it can be effective.

MOON

Apollo Programme may be Docked

SELENOLOGISTS who felt that the Moon was almost within their grasp may have bad news in store for them next week when the future of the Apollo programme is decided. Although the number of scientifically important sites on the Moon is well in excess of the six Apollo flights that now remain, the National Aeronautics and Space Administration has long been toying with the idea of cancelling two of the flights so as to conserve the Saturn V launcher vehicles for ambitions nearer home, such as Skylab and the space station project.

The decision on whether to cancel the two Apollos is being weighed up by the Space Science Board of the National Academy of Sciences as well as by NASA's own Lunar and Planetary Missions Board. The two boards will report next week to a NASA management group which will then decide the future of the programme. Now that production of the Saturn V rocket has ceased, NASA has only seven vehicles left with which to continue the Apollo programme and to launch a Skylab, in which the third stage of a Saturn V would be fitted out as a workshop where astronauts would live and undertake experiments in Earth orbit. In these straitened circumstances, and without a back-up for the Skylab project, the chances of retaining six Saturn V rockets for the lunar landings have always seemed poor in view of NASA's need to be seen to be conquering new worlds. Although eventually the production of Saturn V rockets must be resumed if NASA is to live, the short term advantage of cancelling two Apollo flights will be to free a second Saturn for the Skylab and to keep one in reserve for launching a predecessor of the large manned space station that is planned for the late 1970s.

Deleting another two Apollo flights—the projected Apollo 20 has already fallen by the wayside—is likely to cause some distress and discouragement to lunar geologists who may find their researches left hanging in the air with crucial questions unanswered if the exploration programme is stopped too soon. A site in the lunar highlands has yet to be visited and even when that priority is fulfilled no selenologist will feel his appetite sated until a mascon basin has been inspected together with other unique features such as sinuous rills and Maar-type craters.

The remaining Apollo flights are of two types, known as H and J missions, of which the latter are equipped to allow for longer sojourns on the Moon's surface. If the decision is taken to curtail the programme, the last flight of each type, Apollos 15 and 19, will be dropped. Apart from the priority of visiting the Fra

Mauro highlands site, where Apollo 14 is scheduled to land in February, the remaining sites have not been decided because of the uncertainty that has prevailed about the programme's extent. With Apollo 14 already allocated, lunar geologists may soon face the invidious problem of how to maximize their knowledge of the Moon with only three further shots. Like the girl in the fairy tale, they will doubtless ponder carefully before spending their three wishes.

Peruvian earthquake—the photograph, taken by a NASA aircraft to help assess the extent of the damage, shows the mound of silt that buried the town of Yungay and 20,000 people. A slab of granite, dislodged by the earthquake from the Nevado de Huascaran, picked up glacial silt equal to about three times its volume and sailed down the canyon on a cushion of air. Most of the avalanche swept into the Santa River, but one tributary (to the left of the main flow) leapt over a 600 foot ridge and through the town of Yungay.

Miscellaneous Intelligence

Overheard in the Daddario Committee Room:

HANDLER: Chairman Miller, Mr Daddario, members of the committee, I am somewhat embarrassed in the sense that this very week there is an editorial in *Nature* magazine saying that I am the only scientist in Washington who can give a speech without notes.

I come before you with a rather lengthy statement. With that apology I will try to get on as rapidly as possible.

DADDARIO: We will try to keep it off the record so *Nature* magazine won't know about it.

HANDLER: They will know about it this afternoon.

NEWS AND VIEWS

Satellite DNA Sequence

WHAT possible function can be served by a DNA which consists of tandem duplication of a sequence of only six base pairs, and why should an animal such as the guinea-pig require some 10^7 copies of this short sequence in all its cells? Those are two of the intriguing questions which arise from the analysis of the base sequence of guinea-pig satellite DNA reported by Dr E. M. Southern on page 794.

Since satellite DNA was discovered some ten years ago, it has become increasingly clear that this fraction of DNA has remarkably curious properties (*Nature*, **225**, 899; 1970). It differs in buoyant density from the bulk of the cell DNA but, more importantly, the two strands of satellite DNA that are separated by heating reassociate very much faster than the rest of the cell DNA. This characteristic property of rapid renaturation implies that satellite DNA is highly reiterated and comprises a series of repeats of a short sequence. The length of the repeated sequence can be estimated from measurements of the rate of renaturation and on this basis it seems that mouse satellite DNA, which accounts for no less than 10 per cent of the total DNA in mouse cells, consists of multiple copies of a sequence of about 300 base pairs. By the same criteria the repeated sequence of guinea-pig satellite DNA has been estimated as 10^5 base pairs.

There are of course many pitfalls in making such estimates from renaturation data. Southern's chemical analysis of base sequences of guinea-pig and mouse satellite DNA proves how wildly inaccurate they can be. He finds that the basic sequence of guinea-pig satellite DNA is only six base pairs long and the sequence of mouse satellite DNA is somewhat longer—between eight and thirteen base pairs.

At present there are no enzymes for the cleavage of DNA which are as specific as the various ribonucleases used to cleave RNA. As a result the analysis of the sequences of DNA lags far behind comparable analyses of RNA. If, however, the two strands of a DNA can be separated, it is possible to derive the sequence for the whole molecule because reaction with diphenylamine degrades purines and liberates tracts containing only pyrimidines. Because base pairing occurs only between purines and pyrimidines the complete sequence of a DNA can be deduced from the patterns of pyrimidine tracts obtained when the two complementary strands of DNA are analysed separately. Fortunately some satellite DNAs are among the few species of DNAs which can be analysed in this way, because the complementary strands can be separated by sedimentation in alkaline caesium chloride gradients.

Using this approach, Southern finds that the basic

repeating sequence in guinea-pig satellite DNA is C-C-C-T-A-A in one strand and G-G-G-A-T-T in its complement. But if this satellite DNA consists purely of repeats of this extremely simple sequence, why do the kinetics of its renaturation suggest that the sequence is longer by several orders of magnitude? Southern believes that the answer is simply that during the course of evolution point mutations accumulated in the millions of copies of this short sequence. For example, the strand containing C-C-C-T-A-A has about 4 per cent G even though the basic repeating unit contains none of this nucleotide. Such mutations tend to mask the basic repeating unit and of course they also decrease the rate of renaturation of the two strands of satellite DNA. Estimates of the length of the repeating sequences obtained from the kinetics of renaturation are therefore bound to be overestimates. According to Southern's calculations, to produce guinea-pig satellite DNA the six-base sequence must have been reduplicated, either in one step or gradually, 10^7 times and more than 10^6 point mutations have accumulated. At first sight this seems an extremely large number of mutations, but the estimate is compatible with acceptable estimates of the mutation rate and the evolutionary age of satellite DNA.

What are the implications of this work? First, it is clear that satellite DNA is unlikely to code for any protein. It is inconceivable that the cell should need a protein that is simply a series of repeating dipeptides and it is interesting that of the six possible reading frames for satellite DNA two give alternating nonsense or chain terminating codons. Second, satellite DNA cannot have been subject to a master and slave mechanism because 10^6 mutations have accumulated in what, on an evolutionary scale, is a very short time. Finally, even though we now know the basic sequence unit of a satellite DNA we are no closer to explaining the function of these specialized DNAs. Since they have no role in coding protein the most plausible suggestion is that they have some role in maintaining the integrity of the chromosome itself. The localization of satellite DNA in the centromere regions of chromosomes (*Nature*, **225**, 899; 1970) suggests they play a part in the functions conventionally ascribed to the centromere. But for the time being such suggestions remain speculative. If, however, satellite DNAs really do have some centromeric function they should be present in all eukaryotes, although not necessarily in the large amounts found in some rodents. And Skinner, Beattie, Kerr and Graham (see page 837) report the presence of satellite DNAs, which have greater and smaller buoyant densities than the bulk of the DNA, in five species of crustaceans.

Could Palaeomagnetism be Wrong?

It is now clear that palaeomagnetic data provide the crucial evidence in favour of continental drift, sea floor spreading and plate tectonics, and the other ingredients of what has been called the "new global tectonics" in which the oceans are not only the youngest part of the Earth but are still being formed. The idea of global mobility has become the central dogma of Earth science. Naturally enough, like most dogmas it has attracted uncritical adherents.

Palaeomagnetic data are not the only evidence for global mobility, but they have the advantage of being quantitative. Although palaeontological, geological and palaeoclimatological data are mostly consistent with continental movements defined by palaeomagnetic poles, they usually have the status of supporting evidence simply because they are more difficult to quantify. Thus the doctrine of continental drift is consistent with what is known of the Earth's climatic zone pattern, but the broadness of the climatic zones means that it has been difficult to make precise use of climatological criteria. It has therefore always been an open question as to what would happen if anyone were to compare the results of palaeomagnetism more quantitatively with evidence from other sources.

This crunch has now come, although in a small way. The story is this. Continental movements are determined palaeomagnetically on the assumption that throughout the period covered by the rock record, the Earth's magnetic field has been axially dipolar. Needless to say, this is a reasonable assumption not internally inconsistent, but equally not susceptible to direct proof. Yet without such proof, palaeomagnetism falls to the ground. But Stehli (*J. Geophys. Res.*, **75**, 3325; 1970) now claims, on the basis of an analysis of palaeontological data, that for the Permian the axial hypothesis is not valid. Taken in isolation, his evidence is convincing because it is quantitative. His analysis is based on the observation that certain brachiopods are temperature dependent. The lower the temperature at any given place, the fewer brachiopod families there will be, which means that the diversity of brachiopod families will be a maximum around the equator but will fall off as the latitude increases. That this is the case is shown by the behaviour of Recent clams whose family diversity falls off quadratically with increasing latitude. The problem with Permian brachiopods from the northern hemisphere is that family diversity does not vary quadratically with palaeomagnetic latitude but does so when plotted on the present latitude grid. When plotted on the Permian palaeomagnetic latitude grid the Permian diversity bears no particular relationship to latitude, just as when the Recent clam diversity is plotted on the Permian palaeolatitude grid there is, as would be expected, no simple relationship. In short, the Permian axial field is not consistent with the Permian brachiopod diversity whereas the present latitude grid is. And if this is true for the Permian it could be true for other

geological periods. That is why palaeomagnetists cannot afford to ignore Stehli's conclusions.

The first and most obvious question to ask, of course, is whether the palaeontological sampling was adequate, for clearly the number of brachiopod families detected at a given latitude will be critically dependent on the intensity of sampling. Stehli, at least, is satisfied on this score. In the samples of Recent clams there were sixteen families of "cosmopolitan dominants" which, being more or less temperature independent, were found at more than 70 per cent of the sampling stations. These were used to test the sampling efficiency. On the assumption that perfect sampling would reveal all sixteen families, the number actually discovered at any given sampling station gives a crude indication of the total proportion of families sampled. The cosmopolitan dominants themselves were not included in the diversity calculations simply because they were not temperature dependent and thus of no use in testing latitude dependence.

The second question which can legitimately be asked is whether the palaeomagnetic data from North America and Eurasia are sufficient to define the true geomagnetic field for the Permian. The answer is that they are, as far as it is possible to tell, because the North American and Eurasian poles agree when the two continents are reconstructed in their pre-continental drift positions determined without reference to palaeomagnetism. This is in itself evidence—but not proof—in favour of the Permian axial dipole field because pole positions are calculated using the axial dipole assumption.

If Stehli's analysis is valid—and it is difficult at present to show that it is not—the only conclusion to be drawn in isolation is that the Permian field was not axial. Palaeomagnetic evidence, on the other hand, cannot prove that it was axial but does offer strong evidence to that effect. Palaeontological and palaeomagnetic evidence are thus in conflict, which means, unless some unifying principle is discovered, that one or the other is wrong.

ELECTRON BEAMS

Let There be Light

by our Solid State Physics Correspondent

Two conflicting explanations have now appeared to account for the experiment of Schwarz and Hora in which a beam of electrons was found to be imprinted with the frequency of an impinging laser beam (see *Nature*, **225**, 15; 1970). B. M. Oliver and L. S. Cutler (*Phys. Rev. Lett.*, **25**, 273; 1970) attribute this behaviour to a bunching of the electrons, but L. D. Favro, D. M. Fradkin and P. K. Kuo (*Phys. Rev. Lett.*, **25**, 202; 1970) suggest that the role of the laser beam is to modulate the wave-function of the electrons.

The original experiment (*Appl. Phys. Lett.*, **15**, 349; 1970) has created a great deal of interest. A beam of electrons was passed through a thin crystalline sheet

along which a laser beam was shone. If the laser light is polarized parallel to the electron beam, the frequency of the light is picked up by the electrons and is emitted again when the beam strikes a non-luminescent screen. Apart from the need to account for the mechanism of transfer of the frequency, the experiment may yet have implications for the design of television systems.

Oliver and Cutler suggest that the role of the thin sheet is to provide a short and sharply bounded region in which the electric field is reduced because of the dielectric property of the solid. The crystalline structure of the solid produces Laue spots. Variations of the electric field associated with the laser beam then produce sinusoidal fluctuations in the velocity of the electrons which are equivalent to a bunching of the particles. The effect of the sheet is to reduce the electric field to a level at which the interaction becomes observable. On this view, when the laser radiation is finally emitted at the screen, it should be polarized in a plane determined by the wave-vector of the bunched electrons. This point has not yet been tested experimentally.

Favro, Fradkin and Kuo claim that for usual laser intensities, the velocity imparted by the laser field is too small compared with the spread in velocities of the beam for bunching to take place. They suppose that the light actually modulates the wave-function of the electron, producing an effect which should be observable in synchrotron radiation, bremsstrahlung and Čerenkov radiation.

Both explanations avoid a proper quantum mechanical treatment, the latter being based on the assumption of an electric field created by point particles with unit charge. Oliver and Cutler point out, on the other hand, that although their analysis in terms of bunching seems quite reasonable the first indications of a quantum mechanical treatment suggest that genuine quantum phenomena are present.

ATOMIC ENERGY

Power and the Environment

from a Correspondent

THE availability of power is one of the greatest factors influencing the extent to which man has modified his environment. Less obviously, it is also the key to the ability to reduce environmental pollutants. At the start of the IAEA symposium on environmental aspects of nuclear power stations held in New York from August 10 to 14, Dr M. K. Hubbert (US Geological Survey) showed how rapidly the increasing world population is consuming its power resources. This theme recurred in a symposium principally devoted to the direct impact of power generation on the environment.

A session devoted to the setting and use of standards was chiefly concerned with basic radiation standards, which seemed to be better established than others, as well as being internationally accepted. These standards relate principally to radiation dose to man, and a contribution from Dr A. Preston (Fisheries Radiobiological Laboratory, UK) was typical of many that showed how the standards can be used to derive discharge limits for waste. Widespread use was reported of the technique of estimating the dose to the most highly exposed group of people (often called

the critical group) through the most important route in the environment, which is often a foodstuff. It emerged that detailed procedures had wide variations, chiefly reflecting different national regulatory practices. Reviewing the basic radiation standards, both Drs E. E. Pochin (University College Hospital Medical School, London) and K. Z. Morgan (Oak Ridge National Laboratory) emphasized the caution inherent in the setting of these standards, resulting principally from the assumption of a linear relationship between risk and dose irrespective of dose rate. Standards for air pollution and thermal effects in rivers and estuaries were also discussed but in a much less definitive way.

A series of sessions on the control and monitoring of effluent proved repetitious, although participants concerned with thermal effects claimed to be well satisfied. Outside Britain, monitoring programmes still seem to be proliferating without adequate attention to objectives, and a suggestion by Mr H. J. Dunster (UK Atomic Energy Authority) that monitoring round nuclear installations could be reduced after a few years of operating experience was regarded, especially by delegates from the United States, as interesting but unrealistic.

Contributions concerned with the siting of both nuclear and fossil fuelled power plants were more qualitative than is usual in this highly technical area, and several stressed the importance of gaining public and regulatory acceptance for urban siting. Attempts to bring different types of risk into perspective culminated in contributions from Drs C. Starr (University of California) and F. D. Sowby (International Commission on Radiological Protection). Both gave quantitative estimates of conventional risks which people accept, and suggested ways in which comparisons might be made with the possible radiation risks. These comparisons were difficult, but indicated that radiation risks were much smaller than other risks, such as the 3 per cent chance of being killed at work, to which air crews of scheduled airlines are exposed. Starr also attempted a link to the public awareness of the benefits associated with the risks.

At the end of the final session, on prospects for the future, Dunster welcomed the recent upsurge of interest in environmental matters, an interest which, he said, the power generating industry had been evincing for several decades. He concluded that the symposium had shown that people could be provided with "clean power in sufficient amounts for them to tackle the enormously difficult and pressing problems of man's survival as an advanced social species".

PHOTORECEPTORS

Improving on Nature

from our Molecular Biology Correspondent

ONCE in a while it becomes too great a strain for molecular biologists to maintain their posture of humble seekers after truth, and they give way to the impulse to jolly nature along a little. (Come to that, and mentioning no names, recent developments in molecular biology leave one with the inescapable impression that certain of its mandarins believe themselves to have designed it all in the first place.) An attempt to devise a photoregulation system such as nature might have evolved is described by Bieth, Wassermann, Vratsanos and Erlanger (*Proc. US Nat.*

Acad. Sci., **66**, 850; 1970), and if the philosophy of this approach is perhaps a little like designing the internal combustion engine in order to find out how muscles work, the result is nevertheless a diverting and technically accomplished exercise.

In earlier work from Erlanger's laboratory, enzyme inhibitors were synthesized which were able to undergo reversible photochemical changes to forms of differing activity. One such was an acetylcholine analogue, which could be introduced into electroplax cells from the electric eel, thereby rendering the system photosensitive. A transition from a state of strong to one of weaker activity was elicited by irradiation in the visible, and the reverse process by exposure to ultraviolet. The task, however, that Erlanger and his colleagues set themselves was to achieve a system which could be regulated by sunlight and darkness, and would thus mimic diurnal processes of nature. Success has now crowned their efforts. The inhibitor—again of acetylcholinesterase—is a carbamylcholine function substituted in one of the phenyl rings of azobenzene ($\varphi-N=N-\varphi$), a molecule which is subject to chemically induced *cis-trans* isomerization about the $N=N$ bond. The inhibitor binding constants of the two forms differ by a factor of rather more than two, in favour of the *cis* isomer. The *trans* isomer has an absorption band in the near ultraviolet, where the intensity of bright sunlight is sufficient to cause immediate conversion to a 50 per cent mixture of isomers. (This is New York City at midday in August of last year.) In the dark, or for that matter in the artificially lit laboratory, almost complete reversion to the stable *trans* form rapidly ensues. In these conditions, changes of some 10 per cent in activity of the acetylcholinesterase were triggered by exposure to sunlight, or 30 per cent if an ultraviolet source was used to drive the isomerization to completion. More efficient photoisomerization seems to be possible with a halogenated derivative; but as Bieth *et al.* disarmingly say, they have to await "better climatic conditions" before testing the new system with sunlight, being no doubt consoled during their vigil by the reflexion that the man-made filter of carbon monoxide, sulphur dioxide and tetraethyl lead would have defected nature herself. Bieth *et al.* conjecture that the carotenoids of animals and plants, which as all the world knows are prone to *cis-trans* isomerism, might function as photoregulators, controlling diurnal and seasonal changes in metabolic levels.

Vision is, of course, a system with obvious parallels, for it is triggered by isomerization of the carotenoid, retinene. To bind to the protein, opsin, all-*trans* retinene must isomerize to the bent 11-*cis* form, though the unnatural 9-*cis* isomer will also bind, but not 13-*cis*. One of the curious features of the photoisomerization is the preferential formation of the 11-*cis* form, in spite of crowding at the *cis* bend, caused by the methyl group on the thirteenth carbon in the chain, and the hydrogen on the tenth, which must force the chain into a twisted shape. In the continuing attempt to define the features of the carotenoid that determine its interaction with the opsin, Nelson, deRiel and Kropf (*ibid.*, 531) have synthesized a retinene lacking the 13-methyl group. It turns out that both the 11-*cis* and 9-*cis* isomers of this analogue associate with opsin, but the 11-*cis*, unlike its natural counterpart, binds only weakly, with a sizable proportion of free ligand and protein at equilibrium. It

bleaches normally, however, to the all-*trans* state, though at a very slow rate, presumed to arise from the lower strain energy of the bound *cis* isomer in the absence of the 13-methyl group. Either the difference in shape or the absence of the methyl group *per se* evidently causes the analogue to interact more weakly with the protein. It is perhaps more surprising that it should fit at all. It is known from earlier work that removal of the 9-methyl group likewise leaves a product of which the 11-*cis* form will bind to opsin.

COFFEE

Streamlining the Harvest

by our Botany Correspondent

A COMPOUND which has been attracting attention from plant physiologists for its effects on the ripening and abscission of fruit could have considerable practical value for cultivators of coffee. Trials of 2-chloroethane phosphonic acid (CEPA) on *Coffea arabica* in Kenya (G. Browning and M. G. R. Cannell, *Journal of Horticultural Science*, **45**, 223; 1970) suggest that there is valuable potential for controlling the time of ripening and the thinning of unwanted fruit.

One of the reasons for interest in CEPA at the Coffee Research Station at Ruiru in Kenya is that the cost of picking high quality coffee by hand could be reduced if the length of the ripening period could be influenced. In East Africa, small amounts of coffee sometimes have to be picked from all trees each month, both because the regime of light and dark is continually conducive to the induction of flowering, and because the ripening of fruit from a single flowering is usually spread over several weeks. The advantage of concentrating ripening into a few peak periods to allow for more efficient use of labour is clear.

A further reason for experimenting with CEPA is that it might often be useful to be able to control the abscission of fruit. If, for example, unwanted flowerings could be eliminated, trees might be induced to produce fruit when climatic conditions are most suitable for the development of berries and, subsequently, high quality beans.

As far as abscission is concerned, a single spraying of 1,400–1,500 p.p.m. of CEPA caused 60–65 per cent of young berries to drop at a time when they were expanding rapidly. In a concentration of 1,400 p.p.m. CEPA is not unduly toxic, although up to 10 per cent of leaves may senesce and fall from the trees. CEPA had little or no effect on flowers and berries at any other stage of development, nor did it promote the abscission of ripe fruit. Thus, although it might be possible to use this compound for thinning young fruit, it would not seem to be a potential aid to mechanical harvesting.

There are also promising signs that ripening could usefully be controlled with CEPA, which seems to act by liberating ethylene, the effects of which are well known. In a concentration of 700 or 1,400 p.p.m., a single spraying of CEPA accelerated the onset of ripening, so that the principal period of picking was brought forward by 2–4 weeks. Another good sign was that more ripe fruit was picked from trees sprayed with CEPA than from control trees. There was no shortening of the period of harvest on treated trees, nor was the quality of the coffee beans affected. It

seems likely that CEPA could be used to synchronize the ripening of fruit from flowers which develop a few weeks apart so that picking could be concentrated into fewer periods. Clearly, if more trials prove successful, Kenya's coffee industry could benefit considerably from the use of this compound.

MICROBIOLOGY

Warnings and Advances

from a Correspondent

A NEW awareness of the social responsibilities of microbiologists seemed to pervade the atmosphere of the international congress of microbiology which began in Mexico City on August 9. Setting the scene for the 4,000 delegates, Dr Andre Lwoff (Pasteur Institute, Paris) dwelt on the need for microbiologists to ensure that their efforts are not diverted into such uses as microbiological warfare. He defined their goal as the improved health of mankind, and called on participants to publicize this ideal and remind their governments of the dangers of germ warfare. His point was taken up by the local newspapers which, in giving prominence to the congress, reflected an awareness of the difference between the potential and actual achievements of scientists. Another warning came from Dr S. E. Luria (Massachusetts Institute of Technology) who stressed the powers of microbiologists who can manipulate single genes. It is now practical, he said, to contemplate the possibility of altering the genetic constitution of any kind of living organism, with incalculable consequences.

On a more practical note, Dr Rodrigues-Leiva

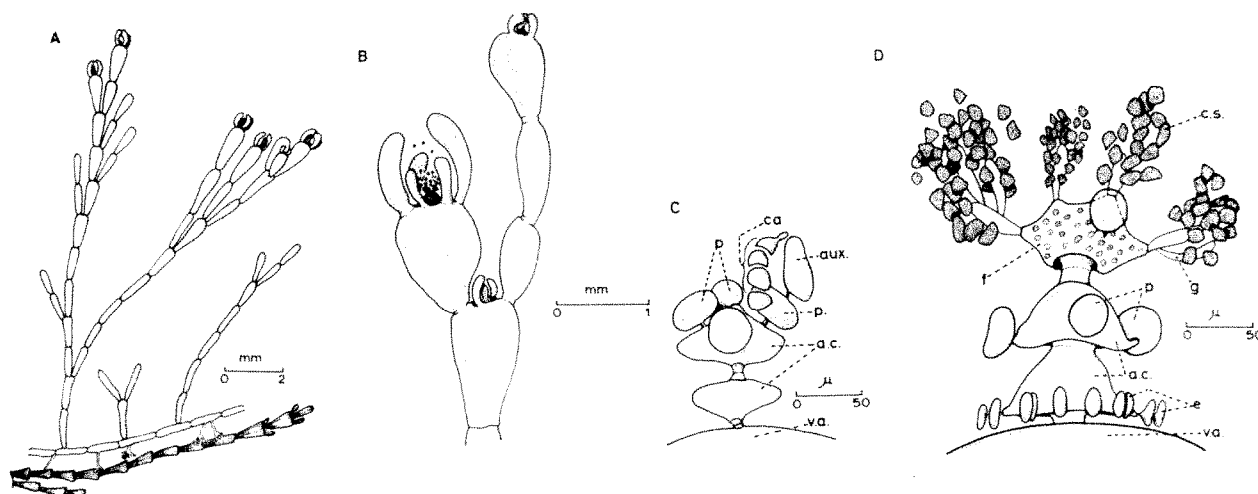

(Chile) pointed out the difficulties that face practitioners of preventive medicine in countries such as those of South America, which have to import all their supplies of vaccines. If adequate quantities of vaccines against poliomyelitis and other prevalent childhood infections could be produced locally, these illnesses could be wiped out easily. But they remain prevalent because of the high costs of importation.

There was more interest for delegates from developing countries in a symposium on single cell protein. They learnt that by growing various bacteria or fungi on readily available substrates, such as cellulose or hydrocarbons, enough first class protein could be manufactured to make a significant contribution to the food supply for man and animals. Several industrial techniques were described, and it was evident that the social and political implications would require vigilance if this new application to human welfare was to be fully exploited.

The principal medical themes of the congress were antibiotics and immunity. Although new antibacterial and antifungal antibiotics were discussed, there does not yet seem to have been a breakthrough on the antiviral front. There are, however, few bacterial or fungal disorders which cannot be controlled by antibiotics. One such group of disorders consists of the infections caused by *Pseudomonas* and similar Gram negative bacilli. Antibiotics are still of limited value in the treatment of these cases, and there is a new awareness of the possible value of active and passive immunization. Several speakers stressed the importance of antibody response in *Pseudomonas* infections and the possibility that it could be enhanced by active immunity.

ALGAE

New Species from the Sea

The shores of southern Africa have yielded six new species of seaweed; one brown and five red algae have been described by R. H. Simons (Division of Sea Fisheries Investigational Report No. 86, Cape Town, 1970). *Griffithsia cymosa*, the red alga, which is shown here, produced a furry growth on a sheet of 'Perspex', which was covered with anticorrosive paint and immersed in the sea in an attempt to discover the sort of organisms that foul the bottoms of ships. The other species described by Simons include *Digenea subarticulata*, which belongs to a genus formerly thought to be monospecific, and *Digeneopsis subopaca*, the first member of a newly founded genus. The brown alga, *Cystophora fibrosa*, was previously thought to be confined to Australasian waters.

In the illustration of *Griffithsia cymosa*, A shows the general habit of the plant; B is the cymose arrangement of cystocarpic segments; C is a fertile dwarf shoot at the apex of a vegetative branch, and D is a stage in the development of the fertile dwarf shoot after fertilization. a, Axial cell of dwarf shoot; ac, auxiliary cell; c, carpogonial branch; cs, carpospore; e, enveloping threads which remain vestigial; f, fusion cell; g, gonimoblast filament; p, pericentral cell; va, vegetative axial cell.

Explosive Nucleosynthesis in Stars

by

W. DAVID ARNETT
DONALD D. CLAYTON

Rice University,
Houston, Texas, and
Institute of Theoretical Astronomy,
Cambridge, England

Recent calculations provide convincing evidence that the naturally occurring nuclei were produced in explosions. The required temperature, density and expansion rate strongly suggest that before the explosion the objects were ordinary evolved massive stars. We review these new developments and present a new table indicating our hypothesis concerning the origin of the nuclei in the mass range $20 \leq A \leq 62$.

IN 1957, Burbidge, Burbidge, Fowler and Hoyle set the stage for at least two decades of research into the origin of the elements. They expressed¹ the opinion that the requirements for a proper theory "are mainly satisfied by the fourth theory in which it is proposed that the stars are the seat of origin of the elements. In contrast with the other theories which demand matter in a particular primordial state for which we have no evidence, this latter theory is intimately related to the known fact that nuclear transmutations are currently taking place inside stars".

In the following year Schwarzschild's monograph, *Structure and Evolution of the Stars*, systematically discussed the exciting progress in understanding static stars, which astronomers had long observed to be virtually unchanging. For the computational problem he observed²: "It is this constancy of stars which makes a definite analysis of the stellar interior possible. It asserts that the stellar interior must be in perfect equilibrium and thus limits the necessary analysis to equilibrium configurations". It was natural then that nuclear physicists interested in the thermonuclear origin of the elements should turn their attention to the details of the thermonuclear reactions that occur in the static nuclear burning stages of the evolution of the stellar interior. Not only did these studies fill in the details necessary for computation of the slow evolution of the star, but it was often tacitly assumed that the nuclear ashes of these epochs would somehow provide an understanding of the observed abundances of the elements.

In the past two years or so, the situation has changed markedly. In many respects the change was presaged by the discovery by Schwarzschild and Härm³ that the ignition of helium in the hydrogen-exhausted core of a low mass star occurs in the presence of a degenerate electron gas which is providing the bulk of the pressure support. Because the pressure of such a gas does not increase substantially when the temperature rises whereas the rates of thermonuclear reaction increase dramatically with increasing temperature, a brief runaway in the thermonuclear activity ensues (the helium flash). After the degeneracy is removed by heat input, the star in this case quickly expands after only a small degree of nuclear burning to an adjusted configuration where burning can proceed in hydrostatic equilibrium. With the subsequent discovery of the very effective cooling of more evolved

stellar interiors due to neutrino emission, it has become apparent that intrinsically more explosive nuclear fuels, namely, ^{12}C and ^{16}O , may also ignite in a very degenerate electron gas and that in this case the runaway in nuclear reactions may be great enough completely to disrupt the star via a thermonuclear explosion^{4,5}. The high temperature of the explosion, which lasts only a fraction of a second, produces such a high degree of nuclear processing that the expelled thermonuclear products are vastly different than the composition of the mass zones before the explosion^{5,6}. The main point we wish to make in this article is that the natural abundances of the elements provide convincing testimony to the fact that they were indeed synthesized in just such events.

The idea that the bulk of the newly created elements were ejected from supernovae is certainly not new; indeed, important papers^{1,7} gave prominent attention to supernovae as a chief source of new matter for the interstellar medium. The recent dramatic progress stems from the realization that the composition of the entire star probably changes in a few explosive terminal seconds and from the development of accurate numerical computation programs for the network of nuclear reactions that proceeds during the explosion. The results of these explosive chains of nuclear reactions can now be seen to be virtually identical to the abundances of the elements and their several isotopes.

Simulation of the Event

To follow realistically the results of nuclear burning in an exploding star we need three key types of information: (1) an understanding of the mechanism of the explosion and the time history of the temperature and density of the exploding matter during the ensuing expansion; (2) knowledge of the composition and state of matter before the explosion; and (3) understanding of the rates of large numbers of thermonuclear reactions. Much experimental and theoretical work remains to be done on the cross-sections of thermonuclear reaction, but due largely to the work of Fowler and his colleagues⁸ on assembling and analysing nuclear data and to the work of Cameron and his colleagues⁹ on the statistical evaluation of thermonuclear cross-sections for the interaction of protons, neutrons, alpha particles and γ -rays with target nuclei primarily in the range $20 < A < 60$, we have estimates of cross-sections which are adequate for the task of

surveying the likely results of explosive burning of nuclear fuels of intermediate mass. With these rates Truran and Arnett and their colleagues have constructed numerical reaction networks appropriate to the explosive conditions and fuels.

The key thermonuclear feature of explosive burning is that the several fuels combust (in the nuclear sense) at temperatures considerably higher than those at which the same fuels burn in an object in hydrostatic equilibrium, with considerable effect on the abundances of the ejected matter. The overheating may result either from the fact that the fuels first ignite in a degenerate electron gas or, for the non-central mass zones, from the compressional heating produced as a strong pressure wave propagates outward from an exploding core. In either case, large amounts of thermal energy are liberated in a time short compared with the star's ability to compensate hydrodynamically, with the result that the entire star may be given positive energy sufficient to disrupt it. In either case the time scale for the expansion should be of the order of the hydrodynamic time scale for free fall or free expansion

$$\frac{1}{\rho} \left| \frac{d\rho}{dt} \right| \equiv \frac{1}{\tau_{HD}} \approx (24\pi G\rho)^{\frac{1}{2}} = \frac{1}{446 \rho^{-\frac{1}{2}}} \text{ s}^{-1} \quad (1)$$

where the mass density ρ is expressed in c.g.s. units. Although large amounts of energy are liberated initially the subsequent expansion should be nearly adiabatic

$$\rho T^{-3} \approx \text{constant} \quad (2)$$

The investigations so far have combined equations (1) and (2) with an estimate of the initial density and peak temperature of the explosion to yield an estimate of the thermal history of the expanding matter. The nuclear reaction codes then explicitly compute the nuclear abundances established during the explosion.

The initial composition and thermal conditions must be generated by computing the complete evolution of the star up to the point of explosion. When that is accomplished, the complete evolution through the explosion will also be done explicitly with hydrodynamic techniques, but for the time being the most dramatic results have been obtained by simulating the explosion with the aid of equations (1) and (2) and judicious guesses concerning the initial state.

Nuclear Evidence

The first indication of the importance of the dynamics of the expansion on the final nuclear products came in a study of carbon burning. Arnett and Truran¹⁰ established a numerical scheme for solving the nuclear reaction network that results when ^{12}C nuclei begin to undergo the fusion reactions

A large number of coupled reactions become possible as the liberated protons, neutrons, and alpha particles begin to react with all of the nuclear species generated within the gas; in fact, Arnett and Truran used rates for 99 different nuclear reactions in their carbon burning network. Despite this complexity, the results they obtained for the final abundances following carbon burning at a constant temperature near 10^9 K, a value at which carbon

would be expected to burn in the core of a star in hydrostatic equilibrium, were very simple. Only ^{20}Ne , ^{23}Na and ^{24}Mg were produced in substantially significant quantities, and approximately in the ratio of their abundances as observed in the solar system. Although this work confirmed that these three nuclear species almost certainly owe their high natural abundance to carbon burning in stars, it left the source of the other isotopes in this mass range a mystery.

Fig. 1. Products of explosive carbon burning. Circles are used to represent solar system abundances by mass, solid lines connect all stable isotopes of the given element and calculated abundances are shown by crosses. The vertical axis is measured in arbitrary units of abundance by mass, X ; the horizontal axis in units of atomic number A . The peak temperature was 2.0×10^9 K, the peak density $\rho = 1.0 \times 10^5$ g cm⁻³ and the neutron excess was $\eta = 0.002$ (see text).

At this time it occurred to Arnett⁵ to make an important numerical experiment. He supposed that for one or a combination of the reasons mentioned earlier, the carbon could be forced to ignite explosively at temperatures near 2×10^9 K, which is far in excess of temperatures at which carbon naturally burns in a static object, and at initial densities in the range $10^5 < \rho(\text{g cm}^{-3}) < 10^9$. A coupling of equations (1) and (2) to the same nuclear reaction network resulted in dramatic changes in the final abundances. A typical result is shown in Fig. 1, where the open circles indicate Cameron's relative solar abundances¹¹ and the crosses represent the final abundances calculated with the reaction network. Before the explosion the gas was taken to be virtually half and half ^{12}C and ^{16}O as produced in a previous epoch of helium burning, plus 2 per cent of ^{18}O which is the result of the earlier conversion within the same star of all of the original CNO nuclei into ^{18}O by hydrogen burning and helium burning in turn. In the computation of Fig. 1 the carbon has burned furiously for about one-tenth of a second at which time reactions are frozen by the falling temperature associated with the vigorous expansion of the gas. Most of the carbon and virtually all of the initial oxygen remain unburned, such that the final ratio $^{12}\text{C}/^{24}\text{Mg}$ matches the solar ratio. More significantly, the nuclei ^{20}Ne , ^{23}Na , ^{24}Mg , ^{25}Mg , ^{26}Mg , ^{27}Al , ^{28}Si and perhaps ^{30}Si and some ^{31}P , are produced in ratios closely approximating the solar abundances. The fact that abundant ^{28}Si is unaccounted for is no weakness, because it is known to be a primary result of oxygen burning. The suggestion is strong, therefore, that these nuclei owe their existence to the explosive ejection of partially burned shells of carbon.

An especially important aspect of the explosive carbon burning is that the final abundances of nuclei having more

neutrons than protons (for example, ^{23}Na , $^{25,26}\text{Mg}$, ^{27}Al) depend on the degree of neutron enrichment initially present when the ^{12}C begins to burn, because there is inadequate time during explosive burning for beta decays to increase the neutron number per gram. The neutron excess is largely due to the isotopes of C, N and O present in the initial composition of the star, constituting roughly 2 per cent by mass in the Sun. Before carbon burning ignites, these isotopes will have been converted to ^{14}N during the CNO cycle and to ^{18}O during helium burning. There results a neutron excess

$$\eta \equiv \frac{n_n - n_p}{n_n + n_p} \quad (3)$$

which has the value $\eta \approx 0.002$ for a composition like the Sun. It is these excess neutrons, roughly 0.2 per cent by mass, that end up as the neutron rich products ^{23}Na , $^{25,26}\text{Mg}$ and ^{27}Al . We will return to this question later in discussing differences in nucleosynthesis between Population I stars and Population II stars. For the time being, we point out Fig. 2, which shows how the abundances of several elements (including specifically Na and Al) depend on the neutron enrichment prior to explosive ignition.

A significant thing happens to the heavier nuclei present in small traces when the carbon burns explosively. The burst of neutrons liberated by the primary burning causes a series of neutron reactions on the heavy seed elements, and we have shown that the rare neutron-rich

Fig. 2. Elemental abundances from explosive burning of ^{12}C and of ^{16}O as a function of neutron excess η (see text). The elements of whose most abundant nucleus has an alpha-particle structure are relatively insensitive to variation of η , and with the exception of magnesium they are represented by dashed lines. In the case of magnesium, which is represented by a solid line, the relative abundance of ^{25}Mg compared with $^{26,27}\text{Mg}$ does vary with η . Such an effect might be observable. A heavy solid circle indicates the point on the curve at which both the elemental and isotopic abundances for magnesium have their solar values. The odd- Z elements are also represented by solid lines. Solid circles indicate where their elemental abundances agree with solar values. Note that the solid circles cluster around $\eta \approx 0.002$. This phenomenon is simply explained if the explosive progenitor of the Sun were a Population I ("metal rich") object (see text).

nuclei ^{36}S , ^{40}A , ^{40}K , $^{46,48}\text{Ca}$, ^{50}Ti , ^{64}Ni , ^{66}Zn , ^{70}Zn and ^{72}Ge very likely owe their natural abundances to these neutron reactions (unpublished). This result has special significance because these are almost all of the major nuclei not produced during the explosive burning of oxygen or silicon. There is, in fact, considerable promise that the requirement for manufacturing these neutron-rich nuclei may delineate special features of the thermal history of the carbon burning.

If the peak temperature in carbon burning rises as high as $T_9 = 3$ the ^{16}O also will ignite explosively, thereby driving the temperature even higher. The primary reaction channels for reactions of $^{16}\text{O} + ^{16}\text{O}$ are $^{28}\text{Si} + ^4\text{He}$, $^{30}\text{P} + \text{d}$, $^{31}\text{P} + \text{p}$ and $^{31}\text{S} + \text{n}$, and the corresponding reaction network builds nuclei at $A \geq 28$. A typical result⁶ of the reaction network is shown in Fig. 3. Virtually all of the nuclei having $32 \leq A \leq 42$ are produced in their observed ratio to ^{28}Si in this particular expansion. Only the rare neutron-rich nuclei ^{36}S and ^{40}A are not adequately produced in that mass range; those two nuclei, however, have already been noted as produced by neutron reactions on S, A and Ca seed nuclei present in small amounts in explosive carbon burning. The nuclei ^{28}Si , ^{30}Si and ^{31}P are not adequately produced by this expansion, but other oxygen burning conditions can have a larger yield of those nuclei, and carbon burning also contributed substantially to their abundance. Thus the success of this calculation is so great that it seems that the ideas must be very close to the truth.

Just as in carbon burning, so it is also in oxygen burning that the element abundances of neutron-rich elements, especially Cl and K for calculations like that in Fig. 3, depend on the degree of neutron enrichment in the gas when the oxygen ignites. Selected results are shown in Fig. 2, where we again see that the neutron excess $\eta \approx 0.002$ is close to the value required for synthesis of the solar system abundances of Cl and K. The demand that the neutron enrichment is not too large seems (see Fig. 10 and Table 3 of ref. 10) to require that the oxygen burning mass zones which are explosively ejected have not been processed previously through hydrostatic carbon burning at $T_9 < 1$, or that the explosion is generated before the hydrostatic carbon burning is complete. In any case, we believe that the replication of known abundance ratios will be possible only for specific correct models of the nucleosynthesis event.

As the oxygen fuel is exhausted, oxygen burning merges continuously into silicon burning. Instead of undergoing fusion reactions, the silicon burns by a process called¹² "photodisintegration rearrangement". In this process the ^{28}Si is slowly (compared with other reaction lifetimes) photodisintegrated into seven alpha particles, which are in turn quickly captured by remaining ^{28}Si nuclei, thereby establishing a tail of higher atomic weight attached to ^{28}Si . Because the nuclei having $A > 28$ suffer photoejection reactions more rapidly than does ^{28}Si , however, the capture flow tends to be balanced by the inverse reaction. Bodansky, Clayton and Fowler¹³ and Truran¹⁴ showed that the nuclear system attempts, and usually succeeds, in establishing what they called a "silicon-burning quasi-equilibrium", in which these inverse reactions among the alpha-particle nuclei

$$[A = 4N] + ^4\text{He} \rightleftharpoons [A = 4(N+1)] + \gamma, \quad 4N \geq 28$$

as well as many others involving protons and neutrons, do come into equilibrium. Those authors showed that the large abundances in the range $28 \leq A \leq 57$ reflect dramatic-

Fig. 3. Products of explosive oxygen burning. The notation is the same as in Fig. 1. The peak temperature is 3.6×10^9 K, the peak density $\rho = 5.0 \times 10^5$ g cm $^{-3}$, and the neutron excess $\eta = 0.002$. Note the excellent reproduction of the ratios of most of the more abundant isotopes.

ally the nuclear properties, basically photoejection thresholds, of the nuclei in that range. Subsequent unpublished calculations by Truran and by Woosley have integrated the reactions of the oxygen burning network through a hotter explosive condition than that shown in Fig. 3, so that the tendency of the expanding matter to freeze into a quasi-equilibrium distribution can be tested. A typical result is shown in Fig. 4, where the final frozen

Fig. 4. Products of explosive silicon burning. The notation is the same as in Fig. 1. The calculated abundances shown are a composite of two equal masses of matter processed through extensive, and through complete silicon burning with an explosive history. The peak density in both cases was $\rho = 2 \times 10^7$ g cm $^{-3}$, the peak temperatures were $T = 4.7 \times 10^9$ K and 5.5×10^9 K respectively, and the neutron excess was $\eta = 0.002$ in both cases. The lower temperature case makes ^{56}Ni and the lower- A side of the iron abundance peak while the higher temperature also makes ^{56}Ni as well as the higher- A side of the iron peak.

abundances from oxygen ignition at temperatures near 5×10^9 K are plotted normalized to the solar abundance of ^{56}Fe . The potentially great success in accounting for abundances in the range $44 \leq A \leq 62$ by explosive mass zones similar to this one is self evident.

The overall degree of success in accounting for the nuclear abundances between $A = 20$ and $A = 64$ by explosive nucleosynthesis is summarized in Table 1. Beside each nuclear species is listed its abundance¹¹ on the scale $\text{Si} = 10^6$, the hypothesized explosive source, the abundance calculated by summing the specific results shown in Figs. 1, 3 and 4, and a comment regarding the degree of numerical success we expect to encounter with this approach. The power of ten multiplying each number is enclosed in parentheses. Numerical results for some nuclei are already outstandingly good even though only four specific mass zones of a continuous object have been summed, whereas a few nuclei show only order of magnitude agreement and a few nuclei seem not to be synthesized at all in explosive events. In several cases we have indicated that we anticipate better agreement than was actually obtained by these four mass zones, because our experience so far has shown those particular nuclei to be rather sensitive to changes of conditions. Several important nuclei in this mass range seem not to be due to explosive burning of carbon, oxygen or silicon, and we have indicated that those nuclei are probably due to different circumstances than the ones we have discussed. For example, ^{22}Ne is suspected of being produced during the explosion in the helium burning shells of stars, whereas ^{54}Cr is probably due to the operation of the more quiescent s-process (generally discussed in ref. 12) on ^{52}Cr and ^{53}Cr seed nuclei. Both of these ideas are at present under quantitative investigation. We expect continued rapid progress to inject many subtle new aspects into this outline we are presenting in Table 1.

Astrophysical Comments

The mass zones responsible for the nucleosynthesis we have been discussing have not come from extremely dense objects. If the pre-explosion density were as great as 10^9 g cm $^{-3}$, the temperature would be forced sufficiently high simply to remove the electron degeneracy so that ^{12}C , ^{16}O and ^{28}Si would all be burned into iron-peak nuclei in a time much shorter than the hydrodynamic time scale. To avoid an embarrassing overproduction of Fe relative to those nuclei produced in Figs. 1 and 3 seems to require explosions in massive stars (say, $20\text{--}40 M_{\odot}$), for which the densities are lower and the distribution of mass zones most nearly assumes the required relative proportions. It is not yet clear whether the centre can explode, allowing an outgoing pressure wave to ignite overlying shells, or if the implosion^{7,15} of the evolved core must somehow trigger detonation of non-central shells. The proper dynamic description of the event and the stellar evolution leading up to it remain to be solved quantitatively.

The model of a single event having several concentric mass shells in the differing stages of nuclear burning shown in Figs. 1, 3 and 4 provides an elegant solution to an old problem; why should the relative abundance of nuclei in this mass range remain relatively constant although their absolute concentrations (relative to hydrogen) vary? All that is required is that the relative masses of the explosive carbon-burning, oxygen-burning, silicon-burning and e-process (which is complete silicon burning) shells take on roughly constant proportions in the explo-

Table 1. CALCULATIONS OF EXPLOSIVE NUCLEOSYNTHESIS

Element	A	Solar abundance by mass ¹¹	Explosive process	Calculated abundance	Prospects for agreement
Carbon	12	4.54 (-3)	C-burning	5.0 (-3)	Excellent

sions of massive stars responsible for most of the element production. Such a situation may be nothing more than the natural outcome of the physics governing star formation and evolution.

There is an important exception to the constancy of element abundance ratios; the odd Z elements (which are neutron-rich) require initial neutron excess for their production, as was shown in Fig. 2. Inasmuch as the neutron excess probably results primarily from the operation of the CNO cycle, which is itself a second generation feature of any galaxy the chemical evolution of which has proceeded from a starting point of hydrogen and helium, we would expect the earliest galactic nucleosynthesis to have occurred with smaller values of the neutron enrichment parameter η . This effect would lead one to expect the abundances of the elements Na, Al, P, Cl, K, V and Mn to increase with time in the galaxy less rapidly near the beginning than the elements Mg, Si, S, A, Ca, and perhaps Cr and Fe. An observational test for this effect

consists of ascertaining whether old metal deficient stars are more deficient in the former group of elements than in the latter. They are indeed found to be so, the most dramatic case being the recent study of +39°4926 by Kodaira, Greenstein and Oke¹⁶. In Table 2 we show their abundances of the elements Na, Mg, Al and Si on the scale $\log N_H = 12$, with the solar abundances shown for comparison. Whereas Mg and Si are deficient by factors of near thirty in this old star, the neutron-rich elements Na and Al are deficient by factors of several hundred, confirming that they were produced less efficiently in the beginning. Similar though less extreme correlation can be found in the metal deficient stars HD 122563, HD 161817 and HD 140283 (see ref. 16 for discussion and references). It seems likely that a wholly new diagnostic technique for the early chemical evolution of the galaxy is unfolding.

Table 2. ABUNDANCES¹⁶ IN +39°4926 AND IN THE SUN

Element	Log $N_{+39^\circ 4926}$	Log N_{sun}	$\Delta \log N_{+39^\circ 4926}$
Na	3.80	6.30	-2.50
Mg	5.69	7.36	-1.67
Al	3.23	6.20	-2.97
Si	6.02	7.45	-1.43

One of the most exciting aspects of the theory of explosive nucleosynthesis is that it may be subject to a direct experimental check through gamma-ray astronomy. Several of the prominent nuclei, especially ⁵⁶Fe, are synthesized in the form of radioactive parents, in this case ⁵⁶Ni, which are ejected from the explosion before decaying. In the decay a characteristic gamma-ray spectrum is radiated. Its detection both in individual objects¹⁷ and in the integrated background of the universe¹⁸ seems likely, and could place the science of nucleosynthesis on a firmer observational basis.

The past two years have been the most creative ones for the science of nucleosynthesis since the late 1950s. We have attempted to survey these new developments in the theory, to present an original table of the origin of the nuclei in the mass range $20 \leq A \leq 64$, and to emphasize two new diagnostic opportunities for observational astronomy.

Radio Source Counts from the Ohio Survey

by

BEVERLEY J. HARRIS
JOHN D. KRAUS

Ohio State University,
Radio Observatory,
Columbus

The Ohio survey shows a decrease in the number of faint sources relative to the number which would be expected for a uniform, Euclidean universe. This confirms the results of the Cambridge 5C2 survey at 408 MHz, but the decrease is sharper for the Ohio counts at 1415 MHz.

THREE instalments of the Ohio Sky Survey¹⁻⁴ list about 8,100 radio sources with flux densities above 0.16. (Flux densities (S) are expressed in units of 10^{-26} W m⁻² Hz⁻¹.) These observations were made at a frequency of 1415 MHz and cover an area of about 4.2 steradians, providing the deepest and most extensive survey at frequencies above 408 MHz and the largest number of sources catalogued at any one frequency. These data are used to derive an incremental number-flux density relation which is corrected for effects of noise and confusion. In the usual number-flux density presentation all sources are counted above given flux densities. We have chosen to count sources within given flux density increments, however, so that adjacent number counts and their statistical errors are independent. The index of this incremental relation is 2.5 for a uniform, static, Euclidean universe. For $S_{1415} > 1$ ($S_{408} > 2.4$) the index is 2.7 for the Ohio survey which is in agreement with the Cambridge 4C survey at 178 MHz (refs. 5 and 6), the Cambridge surveys at 408 MHz (5C2 and BP, refs. 7 and 8) and the Bologna (B2) survey at 408 MHz (ref. 9). For $0.16 < S_{1415} < 0.4$ ($0.38 < S_{408} < 0.96$) the index for the Ohio counts decreases to 1.8 or less. This agrees with the trend shown in the 5C2 and B2 surveys at 408 MHz but the decrease in the Ohio count is more dramatic.

The clustering of radio sources in the plane of the sky is investigated. At high galactic latitudes the Ohio sources show no evidence for anisotropy on scales greater than a few degrees but the source density is greater near the North Galactic Spur and within 30° of the galactic plane. Thus any anisotropy in the plane of the sky seems to be associated only with the galaxy and not with extra-galactic objects.

Observations

The Ohio survey was conducted at 1415 MHz using the 260 foot by 70 foot radio telescope¹⁰ of Ohio State University (OSU). The receiver is a Dicke-type radiometer with a refrigerated parametric pre-amplifier¹¹. The resulting system noise temperature is less than 100 K and the r.m.s. fluctuations are 0.025 K consistent with the 8 MHz bandwidth and time constant of 9 s.

The data retrieval and analysis are by automatic digital computer except for manual inspection of the computed output and elimination of spurious sources. The data reduction is based on procedures developed primarily by Dixon¹². Many of the details are given with the published source lists. Essentially uniform observation and reduction procedures were used throughout the survey. Fig. 1 shows the sources found in the regions of sky covered in the three instalments of the Ohio survey used in the present study. Some numerical data for these instalments are given in Table 1. Sky areas surrounding some very strong sources (including the Sun) were omitted from the survey. The flux density scale adopted is within 5 per cent of that adopted in the NRAO catalogue¹³ or essentially the same as that defined by Kellermann¹⁴.

Corrections

There are two principal effects which cause systematic differences between the observed and true number counts. These are:

(a) Errors in measured flux density due to both system noise and errors in the reduction procedure. Comparison of the flux densities of Ohio sources having small angular diameters and $S > 1$ with the accurate values given in the

Fig. 1. Radio sources in the regions of sky covered in three instalments of the Ohio survey between +37° and -36° declination (δ) and 0 to 24 h right ascension (α) (epoch 1950.0) at 1415 MHz. The large dots represent sources of $S_{1415} > 1$ (flux unit), the medium size dots represent sources of $0.5 < S_{1415} < 1.0$ and the small dots represent sources of $S_{1415} < 0.5$. Some clustering of sources near the (North Galactic) Spur and the galactic plane is apparent. The presentation is on a rectangular projection for which the density will show a $\cos \delta$ effect of 25 per cent maximum for the regions covered. This $\cos \delta$ effect was accounted for in the clustering studies discussed in the text.

Table 1. DATA FOR THREE INSTALLMENTS OF THE OHIO SURVEY

Instalment	Dec. range	R.A. range	Area (Sr)	$S_{1415} > 0.16 \times 10^{-26} \text{ W m}^{-2} \text{ Hz}^{-1}$ Total No. of sources	No. of sources per steradian	$S_{1415} > 0.2 \times 10^{-26} \text{ W m}^{-2} \text{ Hz}^{-1}$ Total No. of sources	No. of sources per steradian
II	+19° to +37°	00 h to 16 h	0.64	1,200	1,800	988	1,540
III	00° to 20°	00 h to 24 h	1.22	2,325	1,910	2,070	1,700
IV	00° to -36°	00 h to 24 h	2.36	4,550	1,930	3,777	1,600
Total			4.22	8,075	1,915	6,835	1,620

References: instalment II: Dixon and Kraus¹; instalment III: Fitch, Dixon and Kraus², Fitch³; instalment IV: Ehman, Dixon and Kraus⁴. The first instalment of the survey by Scheer and Kraus⁵ is not included here as it was restricted to sources with $S_{1415} > 0.37 \times 10^{-26} \text{ W m}^{-2} \text{ Hz}^{-1}$.

NRAO catalogue, by Fomalont¹⁵ and by Harris¹⁶, gives an r.m.s. proportional error in flux density of about ± 7 per cent. For the weaker sources confusion errors predominate.

(b) Confusion resulting from the finite resolution of the radio telescope. Included in this category are the following effects: (1) Flux density errors due to many sources below the flux density limit of the survey. These may be roughly represented by a random distribution of standard deviation 0.05. This value was found from an examination of the survey records, and is in agreement with that calculated from an extrapolation of the number-flux density relation to low flux densities. (2) Errors due to confusion by sources near and above the lower flux density limit of the survey, depending partly on the reduction procedure. (3) Masking of the weaker sources by stronger ones. (4) Small scale angular clustering. The effect of source clustering on the number-flux density relation has been shown by Pooley and Ryle¹⁷ to be unimportant on scales greater than several minutes of arc. Most apparent doubles can be explained by a random distribution of radio sources. Physical doubles with separation less than several minutes of arc will be counted as single sources in the beam area of the OSU telescope and have no significant effect on the source counts.

The net corrections to the number counts may be best determined by a complete Monte Carlo analysis (ref. 18 for example). We have taken a simpler approach and deduced the corrections due to masking (part b3) from the partial Monte Carlo analysis by Dixon¹². The effects of the combined errors in flux density due to noise and confusion (part a and parts b1 and b2) have been calculated by convolving the combined flux density error distribution with the number-flux density relation. The latter procedure is similar to that considered by Bennett¹⁹. The results of these calculations are summarized in Table 2, columns 2 and 3 respectively. Column 4 gives the total correction to the number counts determined from the values in columns 2 and 3. The estimated r.m.s. uncertainties are also given in the table.

In deriving a number-flux density curve of cosmological significance, it is necessary to exclude galactic sources. Our investigation of the distribution of sources as a function of galactic latitude indicates that possibly 7 per cent of the total number of the Ohio sources may be galactic. The exact form of their number-flux density relation is unknown. Their inclusion in the number counts will not influence the final result significantly, however.

Number-Flux Density Relation

The observed number-flux density counts for the Ohio survey are given in Table 3. The Ohio number counts per unit flux density per steradian relative to those expected in a universe model for which $n_0 (S_{1415}) = 376 S_{1415}^{-2.5}$ are presented in Fig. 2 by the heavy solid curve with flux densities at 1415 MHz indicated by the inserted abscissa scale. Arrows show by their length the magnitude of the correction. At high flux densities statistical errors ($\propto n(S)^{-1/2}$) predominate. At low flux densities the errors are due to the uncertainties of the systematic corrections. Individual graphs for the three instalments of the survey show no significant differences. The index of the number-flux density relation is 2.7 for $S_{1415} > 1$ decreasing to 1.8 or less for $S_{1415} < 0.4$. These values should be compared

with an index of 2.5 for counts in a uniform, static, Euclidean universe.

Comparison with Other Surveys

We have taken count data from the Cambridge 4C survey at 178 MHz and the Cambridge (5C2 and BP) and Bologna (B2) surveys at 408 MHz. In Table 4 the observed counts for these surveys and the Ohio survey at 1415 MHz are listed for 20 per cent flux density increments. The 178 and 1415 MHz counts were transformed to 408 MHz assuming a Gaussian spectral index distribution having a mean value of 0.7 so that all five surveys can be inter-compared at 408 MHz as shown in Fig. 2. All counts are relative to the same uniform, static Euclidean universe model for which the number per unit flux density per steradian is given by $n_0 (S_{408} = 1385 S_{408}^{-2.5})$. The arrows show by their length the correction for noise and confusion and where possible are those estimated by Gower¹⁸ and Pooley and Ryle¹⁷. For $S_{408} > 1$ the number-flux density curves are in substantial agreement. For $S_{408} < 1$ the Ohio count is significantly below those of the Cambridge 5C2 and Bologna B2 surveys.

Clustering

We have tested the significance of differences between the observed distribution of Ohio sources over the sky and a random distribution. The area covered by the Ohio survey has been divided into boxes of three sizes: 5°, 10° and 20° square. The numbers of sources in each box have been counted for two ranges of flux density $0.2 < S_{1415} < 0.4$ and $S_{1415} > 0.4$. The numbers of boxes containing n sources have been compared with those expected on a Poissonian distribution. Statistical chi-squared tests show that no significant clustering occurs on angular

Fig. 2. Observed number counts of the Ohio and other surveys compared at 408 MHz relative to the number expected for a uniform, static Euclidean universe (given by the horizontal line for $n'(S)/n_e(S) = 1$ for our model) as a function of the flux density (lower limit of 20 per cent increment). At low flux densities the Ohio counts decrease below the Euclidean model more rapidly than the Cambridge 5C2 and Bologna B2 counts. The Ohio sources were observed at 1415 MHz (flux density scale insert) and transformed to 408 MHz (main scale) assuming a Gaussian spectral index distribution having a mean value of 0.7. The five surveys are the Ohio, the Cambridge 4C, 5C2 and BP, and the Bologna B2.

scales of 5° , 10° or 20° except in the region of the North Galactic Spur.

This method does not provide a very sensitive test of clustering so we examined the number distribution of the boxes on the plane of the sky. The 5° boxes containing ten or more strong or weak sources do cluster and the regions are found to contain many extended sources (Ehman, private communication). Their concentration increases toward the galactic plane and the North Galactic Spur, resulting in an excess of about 15 per cent in the number counts within 30° galactic latitude. Their detailed distribution is under investigation. The number-flux density relation of these sources is not well known. Their inclusion in the source statistics will have only a small effect, however.

Further attempts to correlate areas of high source density with Abell clusters and high velocity hydrogen clouds were made, with negative results.

Conclusions

The Ohio counts involving 8,100 sources confirm the trend reported by Ryle²⁰ for the Cambridge surveys

involving a smaller number of sources. For $S_{408} > 1$ ($S_{408} > 2.4$) the number-flux density index is 2.7 while for $S_{408} < 0.4$ ($S_{408} < 0.96$) the index for the Ohio and Cambridge surveys decreases to 1.8 or less. In the Ohio survey (at 1415 MHz) there is a sharper decrease in index at low flux densities, however.

Numerical calculations by Longair²¹ for an Einstein-de Sitter universe show that such a cut-off in numbers of fainter sources may be explained by a sharp decrease in source densities at redshifts $z \approx 4$. Longair finds that the steep slope of the number-flux density relation for later epochs is explained by incorporating either luminosity or density evolution for the most luminous sources.

There is general agreement between the Bologna B2 survey at 408 MHz and the Cambridge surveys at this frequency. This has permitted the difference in source counts with respect to the Ohio survey at low flux densities to be investigated by comparing sources common to both the Ohio and Bologna B2 surveys. Spectral indices between 408 and 1415 MHz have been calculated for 200 unconfused sources having $0.4 < S_{408} < 1.0$. Their distribution is shown in Fig. 3a. Spectral indices between 408 and

*The values in parentheses indicate the lower flux densities of each 20 per cent increment in units of 10^{-26} W m⁻² Hz⁻¹.

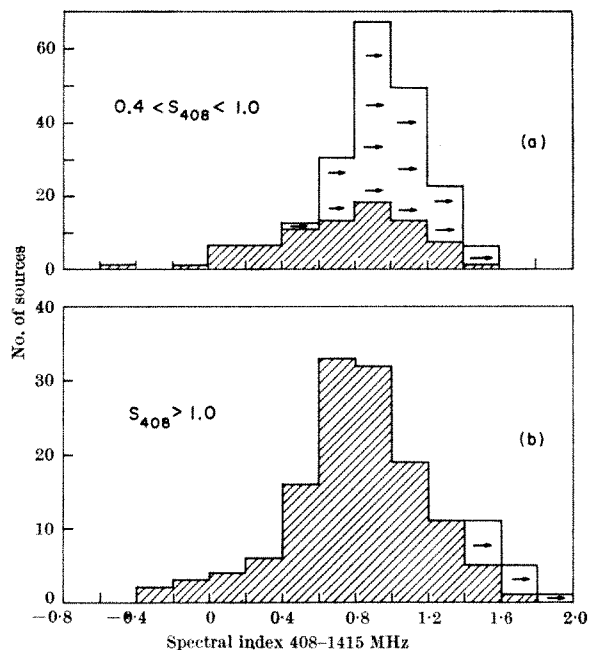

Fig. 3. *a*, Spectral index distribution for 200 Bologna survey sources having $0.4 < S_{408} < 1.0$ for which Ohio 1415 MHz flux densities were available (shaded) or for which no corresponding sources were found in the Ohio survey yielding upper limits for the spectral indices (open). *b*, Spectral index distribution for 143 Bologna survey sources having $S_{408} > 1.0$ for which Ohio 1415 MHz flux densities were available (shaded) or for which no corresponding sources were found in the Ohio survey yielding upper limits (open). A lower limit of $S_{1415} = 0.16$ was taken and at this flux density 60 per cent of the sources should have been found in the Ohio survey.

1415 MHz have also been calculated for 143 sources having $S_{408} > 1.0$. Their distribution is shown in Fig. 3*b*. The open (unshaded) portions of the histograms indicate indices for which only an upper limit could be given, for there were no corresponding sources on the 1415 MHz records. The histogram on Fig. 3*a* for the fainter sources

is displaced toward larger spectral indices as compared with Fig. 3*b* for the stronger sources. This difference could be interpreted as indicating steeper spectra for the fainter sources. This could imply that the more distant and more luminous objects have steeper spectra. Independent evidence has already been advanced that more luminous sources have steeper spectra^{16,22}.

The Ohio State University Radio Observatory is administered by the Department of Electrical Engineering in cooperation with the Department of Astronomy of the Ohio State University with principal support from the US National Science Foundation. The OSU radio telescope is located at the Ohio State-Ohio Wesleyan Radio Observatory, Delaware, Ohio.

Pulsar Sub-pulses and the Emission Process

by

T. W. COLE

Mullard Radio Astronomy Observatory,
Cavendish Laboratory,
Cambridge

This article describes another regular phenomenon in the sub-pulse behaviour of pulsars. The drift speed of successive sub-pulses follows a sawtooth pattern with a linearly increasing drift speed and sudden jumps as the speed drops to repeat the cycle.

THERE is a great variation of structure from one pulsar pulse to the next, although the mean pulse shape obtained by superimposing a train of pulses with the basic pulsar period P_1 remains constant. In certain pulsars (and perhaps all) these variations can be attributed largely to sub-pulses separated in time by the "second periodicity" P_2 (ref. 1) and drifting past the "windows" of the mean pulse shapes at a rate measured by a "third periodicity", defined as P_3 , equal to the mean time between consecutive appearances of sub-pulses at a given point of the mean pulse window. Because the number of sub-pulses appearing in the windows of a train of pulses varies regularly, the third periodicity also manifests itself² as a peak in the power spectrum of the pulse energies. The fact that a similar sub-pulse structure (F. D. Drake, URSI Assembly,

Ottawa, 1969, and ref. 4) and intensity reappear in several successive pulses suggests that an underlying pattern in the mechanism responsible for sub-pulses persists for this interval. This is borne out by the constancy of the drift rate of any particular chain of sub-pulses, although other chains may have different rates.

The pulsar CP 0808, which has particularly well-defined sub-pulses, has been observed at 81.5 MHz with the four-acre antenna at the Mullard Radio Astronomy Observatory. This is a transit instrument capable of observing sources only while they are within about $\frac{1}{2}^\circ$ of the meridian.

A total power receiver with a bandwidth of 30 kHz was used and the time averaging due to dispersion was 2.8 ms. The period of CP 0808 is ≈ 1.292 s and the mean

pulse length is ≈ 80 ms. The pulses were recorded digitally at 250 samples per second, and Fig. 1 shows some of the observations with each horizontal line representing a time window centred on the mean pulse and with successive windows exactly one pulse period apart. The signal amplitude at succeeding samples 4 ms apart has been quantized so that a circle and cross represent an amplitude greater than twice and three times the standard

Fig. 1. Sections of successive pulses of CP 0808 sampled every 4 ms and quantized such that O and X represent amplitudes greater than two and three standard deviations of the received noise.

Fig. 2. Six representative mean sub-pulse shapes for individual chains of pulses and the mean of these six aligned by eye.

deviation of the noise on the digitized record. The drifting sub-pulses are clearly seen, separated on average by about 55 ms and taking, on average, 11 pulse periods to drift through this sub-pulse separation. In this, as in all other pulsars showing this phenomenon^{3,4}, the drift is from the trailing edge of the pulse to the leading edge. The plot shows that each drifting sub-pulse chain has its own (constant) drift speed which can differ markedly from the drift speeds of adjacent chains. The correlation of intensities of sub-pulses for any particular chain can also be seen.

The mean pulse shape (Fig. 1) is found by superimposing pulses sampled at intervals of P_1 . The mean sub-pulse shape can be obtained by superimposing successive pulses with shifts appropriate to the drift rate of the sub-pulse chain. The six averages shown in Fig. 2 were aligned by eye and a further average taken to give a more general mean sub-pulse shape for the pulsar. This is almost Gaussian and of half power width ≈ 8 ms. Because the effective time constant of the recording system was approximately 6 ms, the true mean sub-pulse is only 4 or 5 ms in half power width, much less than was suspected from previous studies^{3,4}. The narrowness of the individual average sub-pulses in Fig. 2 implies that the sub-pulse chains deviate by less than 5 ms from a straight line during the time (15 periods or 20 s) for the sub-pulse to cross the mean pulse window. The individual drift rates must then be constant to within 5 ms in 20 seconds or 1 part in 4,000. The drift rates of

Fig. 3. Plots of the drift rates of successive sub-pulse chains for four two-minute recordings.

different chains, however, vary within the range 4.0 ms per pulse to 7.8 ms per pulse.

The drift rates of successive sub-pulse chains are plotted in Fig. 3 for four recordings of CP 0808 each lasting two minutes, and it can be seen that the drift rates show a sawtooth type of variation with a linear increase of rate followed by a sudden jump to restart the cycle. This behaviour is also revealed if one tries to fit a constant period to the sub-pulse chains at some reference point in the mean pulse window. The residual phase would have a linearly decreasing slope and a jump of about one cycle to repeat the sequence. The phase plots of refs. 1 and 3 show that just such behaviour has already been seen, but not recognized, in CP 0808, AP 2015 and possibly CP 1919. The same behaviour is seen in P_2 which increases up to 80 ms and then jumps as low as 48 ms. The mean value of P_2 is dependent on which part of the mean pulse is used as reference and can be as high as 62 ms at the trailing edge of the pulse. In ref. 3 it was found that for CP 0808 the jump occurs about every 200 pulse periods. It seems that P_3 must be defined with care. If it is defined by observations between jumps, it will be smaller than if it is taken as the average over a long record of data which includes several jumps. The value of P_3 has been found to be $11.1 P_1$ when measured by the sub-pulse drift rate⁴ and to be $11.7 P_1$ when measured by the power spectrum of the intensities of a long succession of pulses². If these two values correspond to the two ways of defining P_3 , there must be a jump every $11.1 \times 11.7 \times P_1 / (11.7 - 11.1) = 220 P_1$, in good agreement with the value given in ref. 3. It seems reasonable then to define a periodicity P_5 as the mean time between jumps in the observed drift rate.

For pulsars MP 0031 and CP 1919 a fourth periodicity P_4 has been observed⁹ which is close to the time for the sub-pulse to drift through the basic pulse period P_1 . It seems that⁹ after the time $P_4 = P_1 P_3 / P_2$, the same sub-pulse could reappear in the mean pulse window. In using the formula for P_4 , the various periods will have to be very carefully defined because they obviously vary throughout the sawtooth cycle.

A theory of pulsars which explains many of the radio observations is that proposed by Radhakrishnan and Cooke⁵ and extended by Komesaroff⁶. In this theory radio emission comes from the region just above the magnetic poles of a rotating neutron star with an inclined magnetic axis. We may suppose that the sub-pulses originate in "concentrations" within this emitting region—an interpretation reinforced by the observations that the polarization of sub-pulses of CP 0328 (ref. 7) and PSR 0833 (ref. 8) is, in general, that of the corresponding section of the mean pulse. A sub-pulse is then seen as the rotating neutron star sweeps the concentration past the observer. For CP 0808 at 81.5 MHz the sub-pulse width of 5 ms and the pulse period of 1.292 s imply that the angular width of the beam from the concentration is only 1.5° . Any theory of the generation of the radio

pulses must provide this form of pulse and not that of the mean pulse shape. The narrow beam and constant drift rate also require that the (hour angle) directions of this beam vary by no more than a fraction of a degree from some fixed angular relation to the pulsar meridian.

The problem is then to explain (i) the presence of a region producing a radio beamwidth of only 1.5° , (ii) the maintenance of this region for at least 20 s, (iii) the movement of the region through the pulse window with a speed constant to better than 1 part in 4,000, and (iv) the sawtooth behaviour of the sub-pulse drift rate.

The marching sub-pulse behaviour has been ascribed⁹ to (density) fluctuations distributed quasi-periodically around the circumference of a revolving circumpolar plasma and the corotation radius was suggested as the most plausible site for these. But the strict requirement on the beam direction of the sub-pulse and the direct relation between sub-pulse polarization and mean polarization argue rather for a system rigidly tied to the surface of the neutron star.

Consider then a rotating neutron star with inclined magnetic axis and emission restricted to within a cone around the magnetic poles. The line of sight to the pulsar sees a section through a cone once every rotation of the neutron star—every P_1 , that is. The actual section of the cone scanned by the observer defines the mean pulse shape while the magnetic field directions along the scan define the mean polarization properties of the pulsar⁶.

The presence of successive sub-pulses separated by an angle represented by P_2 and drifting through the mean pulse window every P_3 with increasing speeds is then compatible with the concentrations responsible for the sub-pulses being in a layer undergoing differential rotation and having successive concentrations enter the

Fig. 4. The proposed explanation of the sub-pulse behaviour and an illustration of how the magnetic field latitude is a function of pulsar latitude.

cone at lower and lower pulsar latitudes. There may be a parallel with the motion of sunspots on the Sun which have a rotational period which varies with solar latitude and which appear at lower solar latitudes during the solar cycle. In physical terms the concentrations could be regions injecting plasma out along the magnetic field lines which cut the region.

One can envisage two possibilities for the drift of the concentrations through the cone. They may either descend in latitude or drift at the same latitude. In principle these alternatives could be distinguished by the curvature of the resulting sub-pulse chains in a plot such as that of Fig. 1. In practice, however, the expected differences of curvature are far below the noise level. During its lifetime, the sub-pulse concentration which is assumed to circulate the neutron star to produce P_4 could be at a lower latitude, and hence drift at a faster speed, on its second appearance. This should be capable of observational verification.

Projection of the sub-pulse chains back in time would be expected to give some clue about their generation. If the concentrations descend in latitude as they drift in longitude they may originate along a line at constant latitude as sketched in Fig. 4a. It is difficult in this case, however, to account for the regularity of the jumps in drift rate.

Whether or not the concentrations drift in latitude, they could be projected back to a region of constant longitude at which the concentrations are created at progressively lower latitudes, another cycle starting again at higher latitudes. It can be seen from Fig. 1 that, at a time equivalent to a longitude 30° before the centre of the mean pulse window, the chains of sub-pulses would be repeating at regular intervals (P_3). For CP 0808 $P_3 \approx 14$ s and it may be significant that, for a typical neutron star, this time is of the order of that for an Alfvén wave to travel along a diameter.

Other theories of pulsars have been proposed by Eastlund¹⁰ and Gold¹¹ in which particles trapped in the magnetic field lines of the magnetosphere emit synchrotron radiation seen as pulses as the neutron star rotates. For particles trapped in the Earth's magnetosphere there is an east to west movement of the particle due to the geometry of the field¹². Such a movement

could produce the drift of the sub-pulse, but the sawtooth behaviour is not an obvious feature of these theories either.

The structure of the magnetic field within the emission cone determines the polarization properties of the emitted pulse. The structure must be a function of latitude (Fig. 4) so that it is predicted that the polarization properties of pulses would depend on the relative phase of P_5 . Indeed, it should be possible to trace the path of the sub-pulse through the window by the measurement of polarization angle of successive sub-pulses.

Many pulsars have not yet been observed to have second periodicities. If the cone of emission included many concentrations or they were of long enough lifetime to circulate many times around the pulsar, the resulting sub-pulse behaviour would be greatly confused. Similarly, if the cone's latitudinal extent was large, the polarization properties would vary greatly throughout the cycle of any P_5 and the strong polarization which might be apparent on individual pulses would be smeared in the mean.

The periodicity structure is the clue to the atmosphere of the pulsar, and the sub-pulse shape is the chief clue to the radio emission mechanism. What is needed is a knowledge of the sub-pulse shape and its behaviour as a function of frequency and from pulsar to pulsar. For example, the ratio of sub-pulse width to pulse period is about 0.006 for at least CP 0808, AP 2015 and CP 0328.

I thank CSIRO for a research scholarship and Drs J. Shakeshaft and A. Hewish for discussions.

Superfluid Turbulence in Neutron Stars

by

GEORGE GREENSTEIN

Belfer Graduate School of Science,
Yeshiva University,
New York

The neutron superfluid in most neutron stars should be in a highly turbulent state. If so, this turbulence drastically alters its rotational properties.

A CLASSICAL viscous liquid placed in a uniformly rotating container will (in the steady state) rotate uniformly with the container. Superfluid helium in the same container will rotate as follows^{1,2}. Vortex lines are formed, uniformly distributed through the liquid and all parallel to the rotation axis. They rotate with the container as if they formed a rigid array. The helium flows about the lines in vortex motion. If an average is taken of the superfluid velocity field over many vortex lines the motion appears classical, that is, there is rigid body rotation. Depending on the roughness of the container surface the vortex lines either do or do not firmly attach themselves to it.

Now imagine that the container is steadily slowing down, and that its surface is such that the vortex lines are firmly pinned to it. Because the superfluid is inviscid it will rotate faster than the container. The vortex lines move with the superfluid, but are pinned to the walls; initially straight, they are therefore steadily lengthening and wrapping about the container. The situation is shown schematically in Fig. 1. Every time the superfluid laps the container by 2π radians, the vortex lines wrap once more about the axis. Eventually the wrapping is very tight. Along the equator lines of opposite sense are brought near each other. This situation is unstable; eventually two opposing lines will be brought sufficiently close to

Fig. 1. A rotating superfluid in a less rapidly rotating spherical container. One vortex line is shown. (The arrow on the line represents the sense of vortex motion of the superfluid about the line.) Initially parallel to the rotation axis, it is wrapped as shown after the fluid has lapped the container by 2π radians. The line length has increased in this process, but the projection of this length onto the rotation axis has not.

reconnect, forming a vortex ring and a shorter vortex line (Fig. 2). The ring migrates away, the line steadily lengthens, new rings form and the process continues. As a given ring migrates about, it collides with others and with lines, exchanging impulse with them. Waves will be excited in the vortex lines and rings. Eventually a ring will be broken³ into two smaller rings. These rings will migrate faster, collide more often, and break sooner into still smaller rings. Feynman³ speculates that the ring of smallest possible diameter is in fact a roton. If so, the breaking up of large rings leads in the end to the heating of the fluid. The whole process constitutes a superfluid version of the dissipation of velocity differentials into heat. In the steady state the superfluid contains tightly wrapped vortex lines, no longer parallel to the rotation axis, plus large numbers of vortex rings. This state is the superfluid version of fully developed turbulence.

It is possible that the neutrons within a neutron star form a superfluid (refs. 4–6, unpublished work of Ruderman, and the refs. contained therein). The region of neutron superfluidity begins within or just below the crystal lattice (unpublished work of Ruderman, refs. 5, 7, 8, and the refs. contained therein) thought to form the outer layers of neutron stars and extends up to densities of $\approx 3 \times 10^{14} \text{ g cm}^{-3}$. In the cores of the more massive neutron star models higher densities are reached, and hyperons are present in great numbers. The question of neutron (and hyperon) superfluidity in these cores is unresolved. The protons, but not the electrons, may form a superconductor.

Vortex lines in liquid helium pin effectively to container walls if the walls possess irregularities of the same general size as the vortex cores. The "wall" in the case of a neutron star to which the neutron vortex lines might pin is the crystal, largely composed of nuclei with Z in the range 30–50. The nuclear sizes are then $\approx 5 \times 10^{-13} \text{ cm}$, roughly comparable⁴ with the radii of the vortex cores ($\approx 10^{-12} \text{ cm}$). The thermal vibrational motions of the nuclei in the crystal are small (it is far below its melting temperature). The neutron vortex lines therefore might be expected to pin to the lattice. The lattice, of course,

is slowing down; it is firmly tied to the magnetic field, which constitutes the "pulsar", and pulsars are slowing down. The neutron superfluid within a neutron star might therefore be in a highly turbulent state. If so, this turbulence would have a variety of effects.

(Superfluid turbulence should also occur even if vortex lines do not pin effectively to the crust. This is because the charged particles within a neutron star, which co-rotate with the crust, exert a non-uniform force on each line. This force arises from the scattering of the charges against the neutrons in each line's normal core. The radius of this core, the neutron coherence length, varies with depth within the star, so does the cross-section for scattering, and consequently the force per unit length on the line. The gradient of this force constitutes the shearing force acting steadily to lengthen the line.

(Baym *et al.*¹⁶ have evaluated the force per unit length f on a vortex line due to the scattering of electrons off the neutron magnetic moments. Their result (equation (9) of ref. 16: f is inversely proportional to the relaxation time they give) can be cast in the form

$$f \propto \{n^{1/3} \Delta / \epsilon\}^{-2}$$

where n is the number density of neutrons, ϵ their Fermi energy and Δ the neutron superfluid energy gap. Δ is given in ref. 6. It varies with position by a factor of ≈ 10 . The value of f then calculated varies with position by a factor of $\approx 10^3$. This strong variation ensures that superfluid turbulence will occur.)

(i) Ruderman⁹ has proposed that the long-period "wobble"¹⁰ in the period of the Crab pulsar might be due to a slow oscillation of the neutron vortex lines. The lines are taken to be parallel to the rotation axis and free to move axially. Clearly, if they are pinned to the crust and tightly wrapped, such a mode of oscillation is strongly modified; very likely it is impossible.

(ii) It is well known that fully developed turbulence possesses a turbulent kinematic viscosity $\nu = (\text{mean velocity in a typical eddy}) \times (\text{diameter of the typical eddy})$. But the velocity field of a superfluid about a vortex line is $v = n\hbar/mr$ with $n = 1, 2, 3, \dots$. Therefore $\nu \approx n\hbar/m$. Here m is twice the neutron mass and \hbar is Planck's constant. (This estimate is in agreement¹¹ with observed properties of the turbulent flow of superfluid helium.) This viscosity dissipates any velocity differentials that might exist in the fluid over distances D in a time $t \approx D^2/\nu \approx 500 D^2/n \text{ s}$

Fig. 2. The line in Fig. 1 has reconnected at the equator, shortening the line and forming a vortex ring.

(D in cm). In particular, a region of thickness $\approx \sqrt{n\Omega/500\Omega} (\approx 1/100 \text{ km for the Crab pulsar})$ will be formed just below the outer crystal in which the neutron superfluid corotates with the crystal. The moment of inertia of this layer can be comparable with that of the crystal. (In the event of a starquake^{12,13}, of course, only a very thin layer of superfluid is suddenly accelerated.)

The existence of this boundary layer, produced by turbulent viscosity, fulfils the conditions required for Eckman pumping to begin. This process spins down the neutron superfluid in a time¹⁴ $t_E \approx R/\sqrt{\nu\Omega} \approx 1/\sqrt{n\Omega} \text{ yr}$, where R is the stellar radius. This time scale (one month for the Crab pulsar, perhaps one year for the slowest pulsars) is always short compared with that for the slowing down of the crust. The neutron superfluid, then, will almost exactly corotate with the crust, maintaining only a small velocity differential with it in order to maintain its turbulent state. (Were the velocity differential to go to zero the vortex lines would no longer be continuously stretching; the turbulence would then dissipate away and Eckman pumping would cease.)

(iii) Vortex lines are in a state of tension, the tensional force being $F = \pi \rho (\hbar/m)^2 \ln(d/\xi)$ where $\rho \approx 10^{14} \text{ g cm}^{-3}$ is the superfluid density, d the distance between vortex lines and $\xi \approx 10^{-12} \text{ cm}$ the vortex core radius. The total number of neutron vortex lines in a neutron star is $N \approx 4 \times 10^{15} \Omega$, where Ω is the angular velocity of the neutron superfluid (nearly equal to that of the pulsar). The total torque exerted by the lines on the crust, and through it to the pulsar, is NFR . The moment of inertia of the crust-plus-charged particles is typically $\approx 10^{-2} M_\odot R^2$. The vortex line tension then produces an angular acceleration $\dot{\Omega}_L$ tending to speed up the crust. Numerically $\Omega/\dot{\Omega}_L \approx 3 \times 10^5 \text{ yr}$. This acceleration is large compared with that corresponding to the observed¹⁰ "wobble" in the period of the Crab pulsar; slow vortex line oscillations of some sort might be responsible for the "wobble".

A similar calculation shows that if $\Omega/\dot{\Omega} \lesssim 3 \times 10^7 \text{ years}$ ($\dot{\Omega}$ is the slowing down rate of the pulsar), vortex line tension is insufficient to prevent the lines from being stretched as the crust slows. In the slowest pulsars (those for which $\Omega/\dot{\Omega} \gtrsim 3 \times 10^7 \text{ years}$), however, the vortex line tension is sufficient to equalize the rotation rates of the crust and the neutron superfluid.

Superfluid turbulence can therefore not occur in relatively old pulsars. Furthermore, in old pulsars vortex line tension constitutes the primary interaction (if the lines are firmly pinned) between crust and superfluid. Any difference in rotation rates is damped out in the time a vortex wave takes to cross the star. This time² is vanishingly small for waves of angular frequency equal to twice the rotation frequency of the star.

(In this connexion the following numerical coincidence should be noted. Vortex waves of angular frequency $\omega > 2\Omega$, where Ω is the stellar rotation frequency, propagate with a velocity²

$$c = \frac{1}{2\pi} \sqrt{\frac{A\omega^2}{\omega - 2\Omega}}$$

where

$$A = \frac{\hbar}{2m} \ln \frac{d}{\xi}$$

For $\omega = 2\Omega$, c is infinite. For ω not much larger than 2Ω , c drops to fractions of 1 cm s^{-1} . The time for this wave to cross a neutron star can amount to months. Conceivably, then, the observed¹⁰ "wobble" in the period of the Crab pulsar may be associated with some sort of resonance in the reflexion of vortex waves. Aspects of this problem will be discussed at a later date.)

(iv) The only scatterings that may occur between neutrons and the charged particles in neutron stars take place within the normal cores of the neutron vortex lines.

Baym *et al.*⁴ have shown that the relaxation time for relative motions between charges (which determine the pulsar clock) and neutrons (which constitute the bulk of the neutron star) can approach years. This time is inversely proportional to that fraction of the neutron fluid that is not superfluid, that is, contained within the normal cores of the vortex lines (and rings). If the lines are greatly lengthened the relaxation time is proportionately shortened (it is inversely proportional to the length of line).

It is difficult to estimate the magnitude of this effect. A given line must wrap very many times about the neutron star before opposing ends come sufficiently close to reconnect and form rings. These rings can themselves survive for long times before being broken apart. It should be noted that the simple twisting of a line does not in itself contribute to the effective line length. This is because momentum can only be transferred to a vortex line normal to its length¹⁵. Therefore, only that component of line length parallel to the rotation axis is of significance; as the line twists this component is unaltered (see Fig. 1). Rings will be colliding with lines, however, exciting vortex waves in them. These waves increase the line length projected onto the rotation axis. If the line is wrapped many times about the star, so that its total length is very great, even a small amplitude wave can have a great effect. Finally, it is well known¹ that in superfluid helium vortex rings can survive for long periods of time before breaking up. They are metastable states of the superfluid. In the absence of detailed knowledge it seems safe to say that the relaxation time is decreased by this effect by several orders of magnitude.

(v) My final point is a speculative one. When an uncooked egg rotates it does so irregularly. The yolk inside moves about erratically, and in order to conserve angular momentum the rotation rate of the shell must also fluctuate. The rotating turbulent neutron superfluid must exhibit something like the same phenomenon. Vortex waves will cause the positions of vortex lines to fluctuate irregularly. In general this fluctuation must be a random, rather than a collective, motion. The velocity field, determined by the distribution of lines, will then also fluctuate. Because the line motions are random the amplitude of the angular velocity fluctuation must be very small. Undamped vortex waves have² $\omega > 2\Omega$. These waves would give rise to very rapid fluctuations in the pulsar repetition rate, and over one rotation period the effects of these fluctuations would average to nearly zero. Damped waves with $\omega < 2\Omega$ are also possible. Provided that rings collide with lines sufficiently often to excite them they could give rise to long-term random fluctuations in the pulse repetition rate.

Other fluctuations are possible. For example, in a rapidly rotating neutron star like the Crab there are $N \approx 10^{17}$ neutron vortex lines. Of these about 10^9 are "outermost", and lie directly alongside the outer crust. Their distance to the crust is $\approx 10^{-3} \text{ cm}$. Suppose their positions are fluctuating with a sufficient amplitude so that they are continually being brought against the crust and annihilated. They are also continually being regenerated to conserve the mean number of lines. This number is fluctuating over short periods of time, however. The rotation rate Ω is proportional to N . If the number of "outermost" lines is fluctuating by $\sqrt{10^9}$ then $\Delta\Omega/\Omega = \Delta N/N \approx 10^{-13}$. This is, of course, an exceedingly small fluctuation.

These considerations only apply to the neutron superfluid. The proton superfluid is constrained by the rigid magnetic field to rotate uniformly.

To summarize: the slowing down of all but the oldest pulsars (all but those for which $\Omega/\dot{\Omega} \gtrsim 3 \times 10^7 \text{ yr}$) will twist the neutron vortex lines, leading to fully developed superfluid turbulence. This turbulence drastically alters a slow oscillation of lines that might account⁹ for the "wobble"¹⁰ in the Crab pulsar repetition rate;

it increases very greatly the coupling⁴ between the neutron superfluid and the charged particles within the star; and it may conceivably lead to small random fluctuations in pulsar periods. The Crab "wobble" may also be due to resonance phenomena in the propagation of vortex waves across the star. It should be emphasized that this discussion should apply perfectly well to laboratory superfluid helium as well as neutron stars. It would be very desirable to gain insight into these phenomena by a direct experiment. Superfluid helium could be placed in a rotating spherical container so prepared that vortex lines pin effectively to the walls. The part of the charged particle system in the experiment could be played by the normal component, which will corotate with the container (the temperature should be close to T_λ to provide an appreciable quantity of normal component). Observations of the relaxation time for sudden relative motions between superfluid and container (or the attenuation of second sound) might determine the total line length. Very precise observation might reveal irregular fluctuations in the rotation rate of the container. Something like a "wobble" might be seen. Eckman pumping should commence.

Base Sequence and Evolution of Guinea-pig α -Satellite DNA

by

E. M. SOUTHERN

MRC Research Group on the Mammalian Genome,
Department of Zoology,
University of Edinburgh,
West Mains Road, Edinburgh

Primary structural analysis reveals that the basic repeating sequence in satellite DNA may be much shorter than reassociation studies have indicated.

THE physical properties which define the satellite DNAs of higher organisms are, first, that they are separated from the bulk of the DNA in density gradients¹⁻³ and, second, that they are able to reassociate rapidly after denaturation⁴. Taken together, these properties suggest that the satellite DNAs are composed of short base sequences, strung together in long tandem repeats⁵. Recently it has been shown that satellite DNAs are peculiar not only in their physical properties. The satellites of mouse⁶ and guinea-pig⁷ DNAs are found in the condensed fraction of isolated interphase chromatin. In mouse the sequence is found in the less soluble fraction of metaphase chromosomes⁸, and by the technique of *in situ* reassociation it is found near the centromeres⁹. For the principal fraction of the genome of all organisms there is a linear relationship between genome size and the rate of reassociation¹⁰. Using this relation the reassociation rates of mouse and guinea-pig α -satellite DNA suggest a repeat length of 300-600 (ref. 4) and 10⁵ (ref. 11) base pairs, respectively. There is also strong evidence, both from buoyant density measurements and from hybridization experiments, that these and other satellite sequences differ markedly from each other.

Clearly a knowledge of the base sequence of such fractions might both reveal underlying similarities and limit the range of their possible functions. At present, however, there are considerable difficulties in sequencing DNA, chiefly because of the lack of degradation methods comparable in specificity with the enzymes used in sequencing RNA and proteins. The one base-specific method degrades DNA to tracts containing only the

pyrimidine bases¹², and it is thereby possible to obtain the whole sequence in the degradation products if both strands are available. From this point of view, some satellite DNAs are good materials for sequencing, because the strands are easily separated in alkaline caesium chloride gradients.

Guinea-pig DNA contains at least three satellites¹¹. One of them, the α -satellite which represents about 5 per cent of the total DNA, has such a high bias in the base composition of its strands that it can be obtained as two separate strands when whole guinea-pig DNA is fractionated in an alkaline caesium chloride gradient¹³. In this article I give evidence that the α -satellite of guinea-pig DNA has been formed by the reduplication of a sequence of six base pairs, and modified by the introduction of mutations.

Evidence for a Short Heterogeneous Sequence

RNAs with simple sequences, such as the transfer and 5S RNAs, give relatively few products when degraded by enzymes specific for one or two bases¹⁴. Similarly, DNA degraded by the diphenylamine reaction yields a number of pyrimidine tracts depending on the complexity of the sequence. For example, crab satellite DNA, the simplest natural DNA, which consists mainly of repeating d(AT)¹⁵ should give mainly pTp by this reaction. More complex sequences, such as ϕ X174 DNA, give many more pyrimidine tracts¹⁶. Fingerprints of the pyrimidine tracts from the heavy (H) strand of guinea-pig α -satellite (Fig. 1) show only three strong spots (excluding inorganic phosphate), suggesting a simple sequence. By contrast the

repeat length calculated from the molar yields of some of the minor components gives values up to 2,000 (Table 1). A structure having these characteristics would be a short, repeating sequence with some sequence heterogeneity; the overall appearance of the map would be determined by the basic sequence; high values for the calculated repeat length would derive from the heterogeneity in the sequence. Clear evidence that the sequence is heterogeneous comes from observations on the melting curve and buoyant density of reassociated satellite DNA, which show that the reformed duplex is imperfectly base paired. The simplest kind of heterogeneity would be that introduced into the sequence by point mutations and in this case it would be predicted that the base sequences of the rarer tracts should be related to those of the more frequent, by one or a few base changes. Further, we might expect

base mutation would need an insertion. Sequences which cannot be derived from CCCT by one or two mutations are present in very small amounts, and together account for about 10 per cent of the total phosphate.

The relationship between pyrimidine tracts is more obvious still in the H-strand, where the most frequent sequence is TT and the next in order of frequency are T, TTT, (TTC) and (TC). The tracts in brackets were not sequenced, but irrespective of sequence, they could be derived from TT by one mutation (Fig. 3). C, left out of this list, is more likely to be introduced by transversion in the longer purine tract complementary to CCCT, and it is obvious that T could be introduced in this way, too. In the H-strand, tracts requiring more than one base mutation from TT account for 5 per cent of the total phosphate.

Fig. 1. Pyrimidine tracts from H and L strands of guinea-pig α -satellite. Light and heavy strands of guinea-pig α -satellite DNA, uniformly labelled with ^{32}P , were prepared as described by Flamm *et al.*¹². Caesium chloride and alkali were removed by dialysis against distilled water and the solution evaporated to dryness. The DNA was dissolved in 0.1 ml. of formic acid (66 per cent) containing diphenylamine (2 per cent) and kept at 30° C for 18 h. Water (0.1 ml.) was added and diphenylamine and formic acid were removed by extracting the solution with ether (5 \times 10 volumes). Water and residual formic acid were removed by evaporating the solution in a vacuum desiccator. The residue was dissolved in 20 μl . of 10 per cent sucrose, and applied to a polyacrylamide gel (2.3 per cent in 0.4 \times 90 cm 'Perspex' tubes) in pyridine acetate (1 M, pH 3.5). After electrophoresis (5 mA per tube) until the inorganic phosphate had moved 70 cm, the gel between the inorganic phosphate and the blue marker was squeezed out of the tubes onto a 45 \times 85 cm piece of 'DESI' paper (Reeve-Angel, Maidstone) along a line 4 cm from a short edge. The gel was allowed to dry, the paper wetted with 7 per cent formic acid, and the potential (1.5 kV) applied at right angles to the gel until the blue marker had moved about 25 cm. The paper was dried at room temperature, placed in contact with sheets of X-ray film (Kodak, 'Blue Brand') and kept in the dark for 2 weeks before developing the film. The darker spots were over-exposed to show up minor components. The spot marked with a question mark in H strand has not been identified; others were identified from their position on the paper and their composition confirmed by the analyses shown in Fig. 2.

to see the basic sequence in those tracts which occur most frequently.

The Basic Sequence

The more frequent pyrimidine tracts from the L-strand were sequenced by analysing the products from a partial degradation with snake venom phosphodiesterase, after removing the terminal phosphate residues with alkaline phosphatase, and rephosphorylating the 5'-terminus with polynucleotide kinase and γ - ^{32}P -ATP^{17,18}. The separation of the digests is shown in Fig. 2 and the main sequences are presented in Table 1. It can be seen that these sequences could all have originated from the most frequently occurring, CCCT, by one or two base changes. The purity of the sequences may be judged from the amounts of T, (CT) and (C₂T) in the partial diesterase digests of (C₃T) relative to the amounts of C, CC and CCC, for example. Perhaps the most striking feature of the sequence analysis is the presence of T at the 3' end of all sequences (except those which contain no T). Most of the sequences could be made from CCCT by either a transition or a transversion (Fig. 3). To make either CTCCT or CCTCT by a single

Taken together, the evidence suggests that the basic repeating sequence is

It is unlikely that the sequence is longer than this. An alternative repeating sequence would be

This is less probable than the first because it does not explain the higher frequency in the L-strand of CCCT compared with T, particularly in view of the four times greater chance of destroying the tetramer by mutation. Other more complex repeating sequences can be proposed, but all are internally repetitive. For example, a repeating sequence of a hundred base pairs would contain five CCCT sequences, three CT sequences, and two CCT sequences in the L-strand; and nine TT sequences and two TTT sequences in the H-strand. It seems improbable that such a sequence could arise in any way other than multiplication and divergence of a shorter sequence.

Mutations in the Basic Sequence

The fraction of mutations in the basic sequence can be calculated in two independent ways: (1) The basic repeating sequence for the L-strand CCCTAA contains no G. The present sequence contains about 4 per cent G¹³. If it is assumed that these 4 per cent have been introduced by base changes and that other base changes are equally likely, then because there are six possible base changes

base changes would be needed to reduce the CCCT from one in six to one in twenty-three, and 20 per cent would be needed to reduce TT from one in six to one in eleven bases.

Both calculations assume that all mutations were changes of one base to another: a considerable error might be introduced if a high proportion of mutations were deletions or insertions. The first calculation gives a low value because the mutations in the basic sequence are not

Fig. 2. Separation of the products of partial digestion with snake venom phosphodiesterase of pyrimidine tracts from guinea-pig La DNA. The pyrimidine tracts, eluted from the maps shown in Fig. 1 with 2 M triethylamine bicarbonate, were treated with alkaline phosphatase (10 μ g) at 37° C for 30 min. The solutions were dried, dissolved in 0.01 M acetic acid and applied to small flags of phosphocellulose, which were eluted with the same solvent. The solutions were dried and the residues dissolved in 20 μ l. Tris buffer (pH 7.6, 0.1 M, containing 0.015 M MgCl₂, 0.025 M mercaptoethanol + 1 μ l. of kinase fraction VI and 1 nmole γ -³²P-ATP). After 2 h at 37° C, the solutions were applied to 'DE81' paper and the phosphorylated products separated from excess ATP by electrophoresis in 7 per cent formic acid. The subsequent steps of detection and elution were as described for the original maps. The pyrimidine tracts, which now have a phosphate group at the 5' end of far higher specific activity than the uniform label, were hydrolysed with snake venom phosphodiesterase (0.01 mg/ml. in 0.02 M Tris buffer, pH 8.5). Samples removed at 10 min intervals were applied to (a) 'AE81' paper and separated by electrophoresis in pyridine acetate at pH 3.5; (b) 'DE81' and separated at pH 1.9. In cases where some of the sequences could not be resolved by this simple procedure, certain of the partial digestion products were eluted and put through a similar partial digestion and analysis. For example, T₂C₂ gives T, C, C₂, (CT) and T₂C₂ in the first analysis showing the presence of CCTT with either TCCT or CTCT or both of them. The (TC) spot gave both CT and TC, showing that all three sequences were present.

which will introduce G into the repeating sequence, three which will introduce C, four which will introduce A and five which will introduce T, the total number of base changes can be calculated as $(6/6 + 3/6 + 4/6 + 5/6) \times 4$ per cent = 12 per cent. (2) The basic repeating sequence would contain one CCCT sequence in the L-strand and one TT in the H-strand per six nucleotides. The analyses show that these frequencies in the α -satellite DNA are one in twenty-three for CCCT in the L-strand and one in eleven for TT in the H-strand. Assuming that the losses are the result of base changes in the pyrimidine tracts, or the two flanking purines, it can be shown that 23 per cent

at random frequencies; it can be seen from the base composition¹⁴ that changes from GC to AT have been more frequent than changes from AT to GC. Deviations from randomness are also clear in the amounts of the pyrimidine tracts (Table 1). On a random basis, some of the sequences should be present in equal amounts. For example, the amounts of TCCT, CTCC and CCTT, which all involve changes of C to T, should be equal. This cannot be so, because the ratio of C to T at the 5' end of (T₂C₂) is roughly one, whereas it would be two for equal amounts of the three sequences. The change from CCCT to TCCT has occurred about 10 times more frequently than

Table 1. PYRIMIDINE SEQUENCES PRESENT IN GUINEA-PIG α -SATELLITE DNA

	Pyrimidine isomer	³² P(per cent total)	Calculated repeat length	Sequences present

Results for the L-strand are from a single analysis on a sample containing about 60,000 c.p.m. For spots which are well separated (Fig. 1) the variance is usually less than ± 5 per cent (unpublished observations); inorganic phosphate was determined separately by electrophoresis in the second dimension only. Four analyses were done on H α -DNA; one (about 30,000 c.p.m.) was analysed as the L-strand (Fig. 1), the other three (about 3,000 c.p.m. each) by thin layer chromatography on polyethyleneimine-impregnated cellulose which separates pyrimidine isomers up to octamers (unpublished experiments). Much of the variance in these results comes from the error in counting the small amounts on the thin-layer plates; these values were included because the longer tracts were not separated by two dimensional ionophoresis. The length of a DNA sequence can be calculated from the yield of a pyrimidine tract which occurs only once in the sequence using the formula $L = 100(n+1)/x$; where $n+1$ is the number of phosphate residues in a tract containing n pyrimidines and x is the measured amount of phosphate in the tract as a percentage of the total phosphate. Tracts occurring more than once give lower values for L which should be related to the real length by a simple factor equal to the number of times that the tract occurs in the sequence. For a repeating sequence, L is the repeat length in number of bases (or base pairs for double-stranded DNA).

the change to CCCC; in a random distribution of mutations, these should be equal.

The proportion and distribution of mutations in the satellite DNA are important in relation to the possible modes of evolution of the sequence to be discussed.

Evolution of the Sequence

There is now abundant evidence that the satellite DNAs of the rodents have appeared relatively recently: none of the closely related rodents examined by Hennig and Walker¹⁹ have common satellites and the conclusion is that the sequences have arisen since these groups divided. Similar evidence for the European grasshopper²⁰ shows that this situation is not confined to the rodents. To explain the sudden appearance of millions of copies of a short sequence, representing a considerable fraction of the genome, Britten proposed²¹ that they are produced by what he has called saltatory replication, possibly in a single organism. The sequences are then imagined to spread through the species. Alternatively the sequences might accumulate slowly over a period of time comparable with the age of the species.

To produce the guinea-pig α -satellite by the saltatory process would require 10^7 copies of the basic sequence to be produced at one time. More than 10^6 mutations would then be introduced by subsequent divergence. In this case, non-random frequencies of the mutations might be taken to indicate that selection has acted to favour some mutations over others. An alternative would be to increase the sequence slowly by unequal crossing over. In this case too, the distribution of mutations should be random, in the absence of selection.

If, however, copies of the sequence were produced by a multiplication process and the periods between multi-

Fig. 3. Mutations in the basic sequence. The main sequences found in the H and L-strands of guinea-pig α -satellite DNA can be accounted for as shown, by transitions or transversions in the basic sequence. Alternative mutations such as deletions and insertions could account for some of the sequences.

plication steps were long enough to allow mutations to be introduced, the amount of any mutation in the final sequence would be determined by the point in the multiplication process at which it occurred: a mutation occurring early, when there were only a few copies of the sequence, would be multiplied many times and be present at a higher frequency in the final sequence than mutations occurring late, which would be multiplied less frequently. This process is explained more fully in Table 2. The possibility that the sequence might have evolved in this way disallows the conclusion that non-randomness in the proportions of mutations is a result of selection. Indeed, the presence of such a large fraction of mutations in the satellite DNA shows that the sequence is not stringently conserved, a conclusion which may be justified by contrasting the diversity of the satellite sequences with the apparent homogeneity of 5S RNA²². This RNA is the product of a repeated cistron and heterogeneity of the degree shown by the satellite would certainly have been

Table 2. PRODUCTION OF A HETEROGENEOUS REPEATED SEQUENCE BY MULTIPLICATION OF A SHORT SEQUENCE WITH MUTATIONS INTRODUCED BETWEEN MULTIPLICATION STEPS

Multiplication step	No. of bases	No. of mutations introduced between step n and $n+1$	No. of mutations accumulated
0	b	0	0
1	bm_1	bm_1x_1	bm_1x_1
2	bm_1m_2	$bm_1m_2x_2$	$bm_1m_2x_1 + bm_1m_2x_2$
3	$bm_1m_2m_3$	$bm_1m_2m_3x_3$	$bm_1m_2m_3x_1 + bm_1m_2m_3x_2 + bm_1m_2m_3x_3$
n	$b \prod_{i=1}^n m_i$		$b \prod_{i=1}^n m_i \sum_{j=1}^n x_j$

The fraction of mutations after n multiplications is

$$b \prod_{i=1}^n m_i \sum_{j=1}^n x_j / b \prod_{i=1}^n m_i = \sum_{j=1}^n x_j$$

b is the number of base pairs in the repeating sequence (six in the case of guinea-pig α -satellite). m is the factor by which the sequences are multiplied and may vary from one step to another. x is the fraction of base pairs changed in the time interval between multiplications and again may vary from one step to another; it is supposed that this fraction is the same for the whole genome. It is assumed that all the copies of the sequence, or a fraction with a typical mutation content, are multiplied at each stage; the possibility is excluded that the multiplication process selects for or against mutations. The results show, as expected, that the proportion of a mutation in the final sequence depends on the step at which it is introduced: a mutation occurring between steps 1 and 2 will be multiplied m_2 times more than one introduced between step 2 and 3. The final calculation shows that the fraction of mutations in the sequence is the same as the fraction received by the whole genome over the same period of time.

seen in sequence studies. The 5S sequence has been preserved not only among the multiple cistrons within a species but also among species separated by considerable evolutionary time. The satellite DNA must be much younger than the cumulative time between these species, for it must have arisen since the guinea-pig diverged from other rodents, and the rate of fixation of nucleotide substitutions in the sequence must have been correspondingly higher. Nevertheless, it can be shown that the number of mutations in the sequence is compatible with acceptable values for the mutation rate and the age of the satellite DNA: these are clearly interrelated. Assuming that the mutation rate for satellite DNA is the same as that of the rest of the genome, and ignoring effects of selection, it is evident that a repeated sequence produced by saltation or by unequal crossing over will receive the same fraction of mutations as the rest of the DNA over the same period of time. That this is also true for a repeated sequence produced by slow multiplication is shown by the calculation in Table 2.

The mutation rate has been calculated from the rate of fixation of amino-acid substitutions, presumed to be neutral, in the fibrinopeptides²⁴ as around 4.2×10^{-9} changes per base pair per year. At this rate, $0.2/4.2 \times 10^{-9}$ or about 5×10^7 years would be needed to change 20 per cent of the bases in satellite DNA. The divergence point of guinea-pig from other rodent species has not been fixed precisely, but it could have occurred as long ago as 50 million years²⁵.

Conclusion

The description of guinea-pig α -satellite DNA given by sequence analysis is somewhat different from that derived from the kinetics of renaturation which suggest a repeating sequence of around 10^5 base pairs¹¹. It is likely that the difference is a consequence of the high proportion of mutations in the sequence: a similar, though smaller, discrepancy is found for mouse satellite DNA (unpublished results of A. Carr-Brown, E. M. S. and P. M. B. Walker). This is the first indication that mismatching might have an effect on the rates of reassociation of nucleic acids and it should be borne in mind that all repeated fractions of higher organism DNA give reformed duplexes which are badly matched. It is possible that the rate of reassociation gives a gross over-estimate of the length of the repeating sequence in these cases, too.

The primary structure of the basic repeating sequence seems to rule out the possibility that the DNA codes for a protein. Of the six possible reading frames for the two strands, two give alternating nonsense codons; the other

reading frames could give repeating dipeptides of Pro-Asn, Leu-Thr, Arg-Val, or Gly-Leu.

So far we have been unable to find any relationship between the sequence of the guinea-pig α -satellite DNA and the light satellite of mouse DNA. The latter seems to derive from the repetition and mutation of a somewhat longer sequence (between eight and thirteen base pairs) which includes the sequence of six pyrimidines TTTTTC.

A simple structure for satellite DNA explains other properties which were formerly puzzling. The bias in base composition, especially between strands is expected of a simple sequence. Melting temperatures and buoyant densities different from those predicted from the base composition are expected of a simple sequence by analogy with the properties of simple synthetic polymers, which differ considerably from those of complex sequences^{26,27}.

The DNA used in this work was prepared by Mr James Merriman and fractionated by Miss Mora McCallum. Dr K. Murray provided polynucleotide kinase and much valuable advice on methods of sequencing. I thank Professor P. M. B. Walker, Mr A. Carr-Brown and Drs. W. D. Sutton and B. C. Clarke for criticism.

Requirement of Serum for DNA Synthesis in BHK 21 Cells: Effects of Density, Suspension and Virus Transformation

by

G. D. CLARKE

Lincoln's Inn Fields, London WC2

Cell density, attachment and serum concentration affect initiation of events leading to DNA synthesis in normal cells. Transformed cells are less restricted.

THE growth of fibroblasts in culture is inhibited when the cultures reach a characteristic saturation density¹⁻³, when growth is arrested in the G1 phase of the cell cycle^{4,5}. Similarly, the growth of fibroblasts is also dependent on anchorage⁶—they will not grow in suspension or in soft gel, for example—and on serum⁷⁻⁹, the addition of which can even stimulate dense static cultures to grow². The

characteristics of fibroblasts transformed by tumour viruses are, however, quite different: they continue to grow even in cultures too dense for normal cells¹¹⁻¹⁴; they may continue to grow even in suspension^{15,16} or even, to some extent at least, in the absence of serum^{8,10}.

We have studied the serum requirement of both normal and transformed cells in different conditions of

density and anchorage in the hope of finding a common explanation for all three factors and a reason why infection with a tumour virus should alter these characteristics. Our findings, together with those of Dulbecco¹⁷ (following article), throw light on the events which lead to DNA synthesis.

We have used the BHK 21 hamster cell line (C13 clone) and a polyoma virus transformed derivative (PyJ). The cells were grown in Dulbecco's modified Eagle's medium containing 10 per cent calf serum. The proportion of cells incorporating DNA was measured in plastic Petri dish cultures by counting labelled nuclei after exposure to ³H-thymidine (10 μ Ci) for 20 h, extraction with 5 per cent trichloroacetic acid and overlay with stripping film for 48–72 h. The incubation period involves only the first cycle of DNA synthesis. Neither reducing the concentration of ³H-thymidine sixteen-fold nor adding a nine-fold excess of unlabelled thymidine affected the percentage of labelled nuclei. The calf serum came from large pretested batches stored at -10°C and was used unheated.

We obtained resting cells in G1 phase and depleted of serum factor, by incubating Petri dish cultures containing 3×10^5 cells for 2–3 days in 0.5 per cent calf serum¹⁰ which was then replaced by serum-free medium. Because, after the addition of ³H-thymidine and incubation for a further 20 h, there were very few radioactive nuclei (0.1 per cent), we used this procedure in all our experiments.

Fig. 1. Response of BHK 21 cells to serum concentration in layer culture. Resting BHK 21 cells (3×10^5 per dish) were incubated for 20 h with 10 μ Ci of 23.5 Ci/mmol [methyl-³H] thymidine and increasing serum concentrations. The cultures were then washed three times with Tris buffer (pH 7.4), twice with 5 per cent trichloroacetic acid at 4°C , twice with ethanol, and exposed for 72 h for autoradiography. Labelled nuclei were counted in a minimum of 300 total cells.

Increasing concentrations of serum were added to the resting cultures and at least 300 radioactive nuclei were counted in each experiment (Fig. 1). The percentage of cells incorporating thymidine increases linearly up to about 50 per cent with 3 per cent serum; thereafter the curve flattens, with 80 per cent of the cells labelled in 10 per cent serum. There was some variable cell loss (up to 30 per cent) in the complete absence of serum, but total cell numbers varied little with increasing serum concentration. Although this agrees with Temin's report of a linear relationship for chick fibroblasts initiated by serum¹⁹, we found variations in the curve in different experiments, so that we do not claim a reproducible first order interaction.

Because most nuclei were either heavily labelled or unlabelled at all serum concentrations, it is unlikely that this procedure is measuring variations in the uptake of thymidine.

To investigate the effect of suspension on the response to serum, we suspended resting BHK 21 cells in medium containing 1 per cent 'Methocel' (4,000 centipoises, Dow

Chemical Corporation) and ³H-thymidine at various serum concentrations. After incubation for 20 h in 1 ml. volumes above a solid medium containing 0.5 per cent serum and 0.9 per cent agar (Difco Bacto), each culture in 'Methocel' medium was washed into a Petri dish with 4 ml. of fluid medium containing 5 per cent calf serum and 10^{-5} M unlabelled thymidine and allowed to spread. Autoradiographic counts of the labelled nuclei showed that DNA synthesis was again initiated in proportion to serum concentration. The slope of the curve in Fig. 2, however, indicates that suspended cells are about sixty times less sensitive than anchored cells, so that even 50 per cent serum only initiated DNA synthesis in 12 per cent of the cells. This effect was not caused by the suspending medium because cells anchored in the presence of 'Methocel' medium showed the usual sensitivity of layer cultures.

Fig. 2. Response of BHK 21 cells to serum concentration suspension and layer culture. Layer cultures were treated as in Fig. 1; suspension cultures are of 2×10^5 BHK 21 cells in 1 ml. medium containing 1 per cent 'Methocel', ³H-thymidine (2 μ Ci) and increasing serum concentrations. After 20 h at 37°C each suspension was diluted in 4 ml. of 5 per cent serum medium containing 10^{-5} M unlabelled thymidine and incubated in plastic Petri dishes for 5 h to allow spreading. Dishes were then treated as layer cultures for autoradiography.

Suspended BHK 21 cells exposed to high concentrations of serum not only initiate DNA synthesis, but also grow. When these cells were seeded in agar suspension cultures containing 50 per cent serum, 30 per cent of the cells formed small colonies within 7 days.

Cell Density, Wounding and Serum Response

We exposed layers of resting cells originally seeded at different densities to increasing serum concentrations. The proportion of cells synthesizing DNA (Fig. 3) reveals that the serum requirement per incorporating cell increases with the density: in other words, the sensitivity of the cells diminishes. Thus even BHK 21 cells exhibit density dependent inhibition in low concentrations of serum. In standard medium containing 10 per cent serum, the effect cannot be observed because nearly all cells are incorporating even at high densities. Fig. 4 shows the effect of final cell density on the response to a fixed serum dose. The response is greatest at about 5×10^5 cells per dish. Above this density the effect of density dependent inhibition is seen. The reduced response at lower densities is probably caused by lack of conditioning factor(s).

Changes in cell density and topography which lead to DNA synthesis may be produced by wounding dense sheets of cells so that emigration from the edge takes place^{2,18}. To examine the response to serum factor of the emigrating cells, resting cultures at a density of 10^6 per dish were wounded by removing a 10 mm strip of cells with a silicone rubber wedge; the detached cells were removed by washing with serum-free medium, and the response to increasing doses of serum was examined as

Fig. 3. Effect of cell density on the response of BHK 21 cells to serum in layer culture. Cells were plated at different densities as shown, incubated, and prepared for autoradiography as in Fig. 1.

before. In the absence of serum very few cells moved from the layer to the bare area, but as the concentration of serum was increased, the number of migrating cells also increased. We therefore conclude that serum contains a factor which stimulates movement. Compared with cells in an undisturbed layer, the initiation of DNA synthesis in emigrating cells is highly sensitive to serum factor (Fig. 5). In the emigrating zone the proportion of cells labelled is even higher than would be expected in standard cultures of approximately equivalent density (2 to 5×10^5 per dish).

The stimulation of DNA synthesis in chicken cells in monolayer culture by serum can also be mimicked by insulin at high concentrations¹⁹; insulin also stimulates BHK 21 cells to form colonies in agar containing 10 per cent serum (personal communication from Dr I. Macpherson). When serum titrations were done in layer cultures to which insulin (23.1 U per mg, Allen and Hanbury) had been added at 10 μ g per ml. (Fig. 6), we found that the action of low concentrations of serum was potentiated by the hormone but that there was no effect in serum-free media.

Polynoma Transformed BHK 21 Cells

Fig. 7 shows the behaviour of PyJ cells from 2 day layer cultures in 0.5 per cent serum when used for titrations in layer and suspension culture. DNA synthesis occurred in at least half the cells in both layer and suspension, even in serum-free media. Moreover, near maximum response was observed at very low serum concentration (0.4 per cent). Not only do these transformed cells respond more readily to serum, but response is hardly affected by anchorage.

Because the transformed cells incorporated ³H-thymidine in the complete absence of added serum, we had to determine the contribution of the 2 day period in 0.5 per cent serum medium which was used to obtain resting cultures. We found that the transformed cells could not be maintained as layer cultures in concentrations of less than 0.5 per cent for prolonged periods because they detached from the surface. Accordingly, transformed cells from standard cultures were maintained in suspension in serum-free 'Methocel' medium for 4 days. When ³H-thymidine was added for only 3 h to these cultures, about 50 per cent of the cells were labelled. It seems therefore that DNA synthesis can continue long after the cells have been removed from media containing serum, but

that the transformed cells will not divide indefinitely in the absence of serum. The number of cells in both layer and suspension culture in serum-free media fell steadily in spite of the continuously high proportion incorporating thymidine, until no viable cells remained. Thus few, if any, transformed cells are prevented from entering the S phase by the lack of added serum factor, but although they continue to synthesize DNA they may die subsequently before entering another cycle.

Serum Requirement for DNA Synthesis

Our results show that serum induces DNA synthesis in BHK 21 cells in any of the states examined, including suspension, and the number of cells in which this occurs is a function of the serum dose. The probability of response—that is, the slope of the dose response curve—was, however, markedly affected by the state of the cells. Suspended cells were about sixty times less sensitive than cells attached to a surface, while the attached cells showed a three-fold reduction in sensitivity when the density was increased ten-fold. Thus BHK 21 cells are sensitive to

Fig. 4. Effect of cell density on the response of BHK 21 cells to 1 per cent serum in layer culture. The abscissa shows the density of cells as counted at termination of the experiment.

Fig. 5. Response to serum concentration of BHK 21 cells in undisturbed layer and wound edge in same cultures. Resting cultures of 10^6 BHK 21 cells per dish were wounded by wiping a 10 mm strip free of cells with silicone rubber, washed with Eagle's medium and incubated for autoradiography as described in Fig. 1. Counts of the per cent of labelled nuclei were made in a cell layer remote from, and at the edge of, the wound.

density dependent inhibition although the effect, which can be detected only at low serum concentration, is clearly less marked than that shown by many other cell types.

Cells migrating at lower density along the edge of a wounded layer are even more sensitive to serum factor than would be predicted from this reduced density, and we believe that this is caused by a diffusible conditioning factor (unpublished observations). Moreover, the dose response curves for normal cells, although differing in slope, pass through the origin. There is therefore an absolute requirement for serum factor if DNA synthesis is to be initiated, even in situations in which cells respond very readily, such as the edge of wounds.

The increased sensitivity of BHK 21 cells to serum in the presence of insulin cannot be reproduced by physiological concentrations of the hormone; the effect could therefore be caused by an impurity.

As the density of a population of cells increases, the requirement for serum factors of any individual cell in the population before it can start DNA synthesis also increases. The rate of change of this serum requirement, which is characteristic for any cell type, clearly limits the final density to which a population of cells can grow at given serum concentration. The saturation density can be correspondingly modified by increasing or decreasing the serum concentration. But the serum factor concentration in a culture is not likely to be constant, as it will depend on removal or destruction by the cells and on medium changes. The final density of a culture will therefore be a complex function involving many factors. The reason for the change in response to serum which accompanies alterations in shape, attachment to a surface and interaction with other cells cannot at present be explained. Dulbecco¹⁷ concludes that cell topography can affect entry to DNA synthesis independently of serum, but that serum can compensate for this action. Our results with BHK cells do not lead directly to this conclusion, but they are not incompatible with it.

In several respects, virus transformed cells differ from normal cells in their response to serum. First, the initial response is very high because a large proportion of cells are synthesizing DNA even in 0.2 per cent serum. Second, in over half the transformed cells, DNA synthesis takes place in the complete absence of added serum. Finally, there is little difference between anchored and suspended cells. Either the requirement for exogenous serum factor is removed or greatly reduced, or the cell can retain the factor (or its products) from earlier propagation. We have not yet been able to distinguish between these two possibilities, because in spite of their ability to initiate

Fig. 6. Effect of insulin on the response of BHK 21 cells to serum in layer culture. Layer cultures were treated as in Fig. 1, with and without insulin (10 μ g/ml.).

Fig. 7. Response of BHK 21/PyJ cells to serum concentration in layer and suspension culture. 3×10^5 PyJ cells per layer culture were incubated for 2 days in 0.5 per cent serum medium and used for serum titrations as in Fig. 1; suspension cells were treated as in Fig. 2. Broken lines indicate a comparable response of normal BHK 21 cells from Fig. 2.

DNA synthesis, a population of transformed cells cannot maintain itself in the absence of serum. Other classes of serum factor must therefore be required for maintenance²⁰ and for the full growth cycle of cells, whether normal or transformed.

These additional factors are presumably not limiting in medium containing serum, so the ability of transformed cells and the failure of normal cells to multiply in conventional medium, at high density, and in suspension, could be ascribed simply to the differences in requirement for the factor needed for DNA synthesis. In these culture conditions, normal cells are very insensitive to this serum factor, so the cell cycle cannot be initiated. Transformed cells, however, escape the restriction because their ability to initiate DNA synthesis is partially or completely independent of this factor. We do not know whether or not the elimination of the requirement of serum factor for initiation of DNA synthesis is a primary change effected by the addition of the viral genome to the cell. The number of possible viral functions is limited, and it is tempting to suppose that only one or two gene products are ultimately responsible for all the changes in cell physiology such as movement, orientation, surface components and carbohydrate metabolism, as well as increased growth capacity. The removal of the serum factor requirement could be linked to any or all of these changes.

Topoinhibition and Serum Requirement of Transformed and Untransformed Cells

by

RENATO DULBECCO

Salk Institute for Biological Studies,
San Diego, California 92112

The multiplication of tissue culture cells is controlled by several different physiological characteristics, the quantities of which can be measured. Transformed cells are characterized by the values of some of these physiological parameters.

WHEN a confluent culture of 3T3 cells on a plastic Petri dish, in which most cells do not synthesize DNA, is wounded, DNA synthesis is initiated in the cells that migrate into the denuded area^{1,2}. Although this initiation depends in part on the release of cells from extensive contacts with other cells, which seem to inhibit DNA synthesis (topoinhibition, TI), it is clear that other factors are also involved². To study these other factors and their relationships to TI, I have examined the effect of serum, which is required for the growth of many cells, on the initiation of DNA synthesis in cells in the wound and in the cell layer far from the wound, and on other cellular phenomena, using a variety of cell types. The main results presented here are a separation of the effects of serum deficiency and topoinhibition, and the derivation of new criteria for characterizing virus-transformed cells.

The following permanent lines were used for cell cultures: 3T3³, originally from Dr H. Green; BALB/c-3T3⁴, from Dr G. J. Todaro; BHK, a derivative of BHK 21, Cl13⁵, originally from Dr M. G. P. Stoker; BSC-1⁶, a line of green monkey kidney cells; SV3T3⁷, an SV40-transformed line of 3T3 cells, originally from Dr H. Green; PyS4, a polyoma-transformed line of BHK cells produced in this laboratory; H50⁸; SV FL101, a "flat" variant of SV3T3 cells⁹; Cl 32-5 and Cl 41-1, two similar variants obtained in this laboratory from SV3T3 cells. For short-term cultures we used ME, secondary mouse embryo cultures; HaE, secondary hamster embryo cultures; BMK, primary baby mouse kidney cultures.

Cultures were prepared on Nunc plastic Petri dishes in reinforced Eagle's medium containing 10 per cent calf serum, except for BHK cultures, which also received 10 per cent TP (TP = 3 per cent Difco tryptose phosphate in water); BSC-1 cultures, which were grown in medium containing 10 per cent foetal calf serum and 5 per cent TP, and for BMK cell cultures, which had 10 per cent horse serum instead of calf serum. Specific treatments are indicated in the legends to the figures.

Wounding, labelling and autoradiography were carried out as already described². Various regimes of pretreatment were used, and Fig. 1 describes these graphically.

Effect of Serum Concentration on Initiation of DNA Synthesis

Confluent cultures of 3T3, BALB/3T3 or BHK cells were washed with serum-free medium and then covered with medium containing variable amounts of serum (regime B, Fig. 1). Figs. 2A and B illustrate the results. They reveal two features: (1) the proportion of DNA-synthesizing cells in the wound is much higher than in the layer; (2) the ratio varies at different serum concentrations. At low serum concentrations, incorporation in the wound is extremely sensitive to variations in serum concentration. This behaviour affords a sensitive way to measure low serum concentrations (from about 10⁻⁴ upwards).

The proportions of cells in the wound and in the layer

which synthesize DNA are strongly affected by the treatment of the cells before wounding. First, pre-exhaustion of factors in the medium by long incubation before wounding (regime A, Fig. 1, without changing the old medium at or after wounding) markedly reduces the number of DNA synthesizing cells in the layer, but has little effect on incorporation in the wound (Table 1). The exhaustion probably affects serum factors because, after one day's exhaustion, the proportion of radioactive nuclei in the layer is very roughly proportional to the initial serum concentration. Second, cultures which were washed when serum factors were still abundant (regime B, Fig. 1) also display high incorporation in the wound in the absence of added serum. If, however, in similarly treated cultures, the serum factors were mostly exhausted at the time of washing, there was very little incorporation in the wound without further serum addition. Third, cultures of BALB/c-3T3 treated according to regime C, Fig. 1, sometimes show a higher proportion of DNA-synthesizing cells in the layer than when phase 3 (incubation in serum free medium) was omitted. The effect, which is only noticeable in cultures to which serum was added in phase 4, is, however, not always reproducible; neither is it clearly shown by other cell lines.

The first effect shows that the serum factors which are required to initiate DNA synthesis in the layer are exhausted more rapidly than the factors which are required to initiate DNA synthesis in the wound; it is not known whether the two types of factors are identical. The second effect shows that some factors have a persistent action, which continues after they have been removed from the medium; they may stick to the cells or cause a lasting cell modification. The third and only occasional effect may perhaps be caused by release from the cells of factors which are able to stimulate the initiation of DNA

synthesis, especially in the layer, but require serum for their action. BHK cells have been shown to produce factors which stimulate DNA synthesis in the presence of serum¹⁰.

The very strong influence of the cell pretreatment may cause variability in experiments conducted in otherwise similar ways, if the pretreatment regime is not closely controlled.

We have extended this approach to a variety of cultures of either transformed or untransformed cells. The results show four types of behaviour, as shown in Figs. 2 and 3.

First, with 3T3, BALB/c-3T3 and BHK cells, the two curves (wound and layer) begin close to the origin, indicating that the initiation of DNA synthesis strongly requires serum, both in the layer and in the wound (Fig. 2, A and B). The ratio of pairs of values of the two curves corresponding to the same serum concentration has its highest value near the origin and then declines as serum concentration is increased.

Table 1. EFFECT OF SERUM EXHAUSTION ON INITIATION OF DNA SYNTHESIS IN CULTURES OF 3T3 CELLS

Serum concentration per cent	Days of incubation before wounding	Cell concentration in 100 × 450 μ fields		Proportion of radioactive nuclei		Prop. rad. nuclei wound/Prop. rad. nuclei layer
		Layer	Wound area of maximum labelling	Layer	Wound area of maximum labelling	
2	1	21.6	12.8	0.008	0.20	25
	2	18.1	7.1	0.006	0.58	97
	3	17.8	4.0	0.004	0.53	132
10	1	38.7	23.2	0.091	0.39	4.3
	2	31.8	12	0.030	0.51	17
	3	28.8	11.5	0.015	0.36	22
20	1	41.3	19.4	0.170	0.50	3.0
	2	49.8	5.0*	0.037	0.70	19
	3	64	14.6	0.006	0.42	70

* This wound was wider than the others.

Cultures were started with 2.5×10^5 cells per 50 mm Petri dish in 10 per cent calf serum medium. After 24 h, the culture medium was changed to one containing the indicated amount of serum. At subsequent times, some cultures were wounded, and after 22–24 h ^3H -thymidine was added at the final concentration of 7×10^{-7} M, 1.2 $\mu\text{Ci/ml}$. After labelling for 6–7 h, the cells were fixed and autoradiographed. Times are measured from the medium change.

Second, ME cultures kept for several days in low serum and then tested behave similarly, but an especially high proportion of the wound cells can synthesize DNA in the absence of serum (Fig. 3A). The proportion is further increased by addition of serum. The wound and layer curves have the same general relationship to each other as in the previous case. Similar results are obtained in HaE cultures.

Third, in cultures of epithelial cells, such as BMK or BSC-1, a considerable proportion of the cells can synthesize DNA in the absence of serum, especially in the wound, and the proportion remains nearly constant as serum concentration is increased, so that the ratio of the proportion of labelled cells in the wound to that in the layer does not change appreciably with serum concentration (Fig. 3B).

Fourth, in cultures of transformed cells, the proportion of DNA-synthesizing cells is either independent of serum concentration or is only slightly dependent, becoming maximal at low concentrations (1 per cent or less); furthermore, there is very little or no difference between the wound and the layer.

Serum Requirements for other Cellular Functions

A requirement for cell survival is demonstrated by the effect of prolonged serum starvation. For most cell types, both untransformed and transformed, the proportion of incorporating cells (irrespective of serum concentration) is higher if they come from a serum-containing culture than from a serum-starved culture. In the absence of serum, death is observed within a day or two, with all fibroblastic cell types, both transformed and untransformed, as shown by progressive cell detachment and accumulation of dead cells in the medium. In cultures in

Fig. 2. Dependence of proportions of radioactive nuclei on serum concentration. Confluent cultures were treated according to regime B, Fig. 1. Labelling was done with ^3H -thymidine, 1.2 $\mu\text{Ci/ml}$, 7×10^{-7} M. A, BHK cells; B, BALB/c-3T3 cells.

which cell multiplication in the layer is blocked by topoinhibition (for example, BALB/c-3T3 cells) the number of attached and morphologically normal cells remaining after a given time is proportional to the initial serum concentration (Fig. 4).

The proportion of cells in mitosis is greatly affected by the conditions of the cultures. In cells showing strong TI (for example, BALB/c-3T3 or 3T3), mitoses are absent or very scarce at any serum concentration. In transformed cell cultures, the proportion of mitotic cells both in the wound and layer depends on the serum concentration. In SV3T3 cell cultures, tested under regime B, Fig. 1, nearly 100 per cent of the cells synthesized DNA, both in the wound and in the layer, at any concentration of

Fig. 3. Dependence of proportions of radioactive nuclei on serum concentration. A, ME cells, secondary cultures prepared with 5×10^6 per 50 mm dish in 10 per cent calf serum medium. After a day incubation they were changed to 0.5 per cent calf serum medium and left in that medium for five days; they were then treated according to regime B, Fig. 1. B, BSC-1 cells, treated according to regime B, Fig. 1.

serum, but the total number of cells entering mitosis depended markedly on serum concentration (Table 2). The ability of cells that have initiated DNA synthesis to undergo mitosis therefore still depends on the serum concentration, which may explain the much more pronounced dependence of transformed cells on serum concentration for growth than for initiation of DNA synthesis (personal communication from R. Holley).

Conditions for the Initiation of DNA Synthesis

The different behaviour of the various cell lines with respect to initiation of DNA synthesis can be described by the following three parameters (Fig. 5):

Table 2. RATES OF MITOSIS IN SV3T3 CELL CULTURES AT DIFFERENT SERUM CONCENTRATIONS

Hours with colcemid (from time zero)	No serum	Serum concentrations		
		1 per cent	4 per cent	8 per cent
7-23	0.010	0.020	0.021	0.024
23-30	0.004	0.034	0.030	0.037
30-47	0.0008	0.012	0.025	0.023

At time zero parallel cultures were washed with serum-free medium, then overlaid with 5 ml. medium containing various concentrations of foetal calf serum and incubated at 37° C. At the indicated times colcemid was added to some cultures (final concentration 0.06 μ g/ml.); the cultures were returned to the incubator; at subsequent times the cultures were washed with saline, kept 5 min in hypotonic saline (physiological saline 1:4 in water), dried, fixed and stained with Giemsa. Mitotic and non-mitotic cells were counted under oil immersion. Numbers indicate proportion of cells entering mitoses per hour. Proportions of radioactive nuclei in parallel cultures labelled with 3 H-thymidine between 7 and 30 h were 99 per cent or higher irrespective of serum concentration.

(1) The serum requirement in the wound (WSR), defined as $\frac{MxWP - MnWP}{MxWP}$ where MxWP is the highest proportion of radioactive cells in the wound at high serum concentration, MnWP is the proportion of labelled cells in the wound without serum. Because the wound cells are maximally sensitive to serum, WSR represents the true serum requirement of the cells, when other conditions affecting DNA synthesis are removed.

(2) Topoinhibition (TI), that is, topographical factors inhibiting DNA synthesis in the layer². TI is defined as the ratio $\frac{MnWP - MnLP}{MnWP}$, where MnLP is the proportion of incorporating cells in the layer at or near zero serum concentration where the ratio is maximal.

(3) Compensation of topoinhibition by serum (CTI) is defined as the ratio $\frac{TI - TIhs}{TI}$, in which TIhs is topoinhibition at high serum concentration (about 10 per cent in these experiments), where it is little affected by small changes of serum concentration ($TIhs = \frac{MxWP - MxLP}{MxWP}$).

CTI is essentially zero in cultures of epithelial cells and is unmeasurable in those of transformed cells. CTI may be affected by cell-released factors, as is sometimes the case for BALB/c-3T3 cells.

Fig. 4. Numbers of cells per microscopic field in cultures of BALB/c-3T3 cells after exposure to various serum concentrations. Confluent cultures were washed with serum-free medium and then covered with 5 ml. of medium containing various concentrations of calf serum. 32 h later the cultures were washed with saline, fixed with 5 per cent trichloroacetic acid, rinsed several times with ethanol and stained with Giemsa. Nuclei were counted using a $\times 100$ oil immersion objective.

Table 3. PHYSIOLOGICAL PARAMETERS CONCERNING INITIATION OF DNA SYNTHESIS IN DIFFERENT CELL TYPES

Cell types	Length of preincubation in SFM	WSR	TI	CTI
Untransformed cell types

UM = Unmeasurable.

(a), (b), (c) indicate repetition of the same experiment.

The three parameters for various cell types are given in Table 3 and are plotted in the correlation diagram of Fig. 6. The diagram shows that WSR, TI and CTI are not obviously related.

The independence of WSR and TI is also indicated by the different effects of pretreatments on DNA incorporation in the layer and in the wound. Partial exhaustion of serum factors strongly affects labelling in the layer (but not in the wound); and cells washed from unexhausted medium retain a memory of the serum factors with resulting high incorporation in the wound (but not in the layer). Other pretreatment regimes (see Table 3) markedly enhance incorporation in layers of BALB/c-3T3 cell cultures but little in wounds. It is therefore likely that TI does not derive from the occlusion of cell receptors for serum factors in crowded layers², but is the consequence of cell interactions that directly affect DNA synthesis. TI is therefore identifiable with contact inhibition of growth, often postulated as a control mechanism of cell multiplication, independently of serum factors.

Different Functions of Serum

At least four functions are indicated by my results, two of which are concerned with the initiation of DNA synthesis. Of these, one is a direct role and is measured by WSR; the other is to counteract TI in cultures of fibroblastic cell types displaying TI (but not in cultures

Fig. 5. Scheme indicating the quantities involved in the determination of the physiological parameters.

Fig. 6. Correlation diagrams for WSR, TI and CTI. The data of Table 3 are used. ○, Untransformed cells; ◐, transformed cells; ●, "flat" revertants of SV3T3 cells. The length of the line attached to some of the symbols is proportional to CTI.

of epithelial cells). Another is to prevent irreversible cell changes, ultimately leading to cell death; the last is concerned with mitosis.

Different factors in serum may be responsible for the different roles. For instance, the cell-survival factor may be different from that involved in WSR, as suggested by the results of Table 1, and also by results of others (personal communication from M. G. P. Stoker).

The control of multiplication of cells varies according to a combination of many physiological characteristics of the cells, of which five can be identified: WSR, TI, CTI, the serum requirement for survival, and for mitosis. For different cells, the quantitative value of each characteristic differs.

These factors play an important part in generating the morphology of cell cultures in standard conditions (that is, with 10 per cent serum in the medium). It is likely that the "thin" or "flat" fibroblastic cultures—that is, with low saturation density—such as 3T3 or BALB/c-3T3, derive their characteristics mostly from their requirement for large amounts of serum, especially to combat TI (CTI effect) and perhaps for mitosis. It is likely, furthermore, that these cultures exhaust serum at a high rate. High TI in itself does not determine a flat phenotype at high serum concentrations owing to the CTI effect of the serum. In fact, ME cultures, which have high TI but also high CTI (and probably also a low rate of serum exhaustion), are not "flat", and reach a rather high saturation density. BHK cells are situated in between, having a moderately high serum requirement and apparently a lower rate of exhaustion. The lines that are commonly used as "normal" in transformation experiments (3T3, BALB/c-3T3 and BHK) are therefore pseudonormal and differ considerably from truly normal cells (such as ME). These lines may have originated by several genetic changes, some in the direction of transformation, and others causing a high serum requirement for CTI and possibly also a high serum removal rate. This possibility is supported by the great ease with which 3T3 and BALB/c-3T3 cells give rise to spontaneously transformed derivatives, and by the mild oncogenicity of BHK cells in hamsters. The use of these pseudonormal cells as normal cells may lead to misinterpretations in many kinds of experiments. For instance, in the study of viral transformation, they may require fewer virus-induced changes than normal cells in order to become transformed.

Characterization of Transformed Cells

The transformed phenotype seems to result chiefly from minimal or absent TI and the concomitant absence

of serum requirement for CTI (Fig. 6). These cells also have low WSR, but in this respect they are no different from epithelial cells. Serum requirements of transformed cells for mitosis and for survival, however, are not small. These physiological properties are, to a large extent, independent of the morphological characteristics of the cultures, for several "flat" revertants (as described by Pollack⁹) would still be classified as transformed on the basis of WSR and TI, whereas others show intermediate properties (see Fig. 6). All the "flat" revertants, however, show a higher serum requirement for mitosis than SV3T3 cells. This shows that genetic changes can cause a dissociation of some physiological properties from others and from morphological properties. The latter point has already been demonstrated by other means (personal communication from M. G. P. Stoker). The physiological properties described in this article can contribute to a more precise definition of the transformed state.

Because transformed cells grow as neoplastic cells in animals, topoinhibition is probably an important mechanism regulating cell multiplication in organisms in normal conditions. The humoral factors that also control cell multiplication in animals may interact with topoinhibition. The observation that when cells are transformed by viruses they change simultaneously in several physio-

logical parameters (for example, TI and WSR) contrasts with the apparent independence of these parameters of each other. There is no contradiction, however, in these observations, for the transforming virus may affect several cellular functions through the simultaneous expression of several of its genes. Studies with viral and cellular mutants, now in progress, may clarify this point.

Genetics of a Molluscan Vector of *Schistosomiasis*

by

CHARLES S. RICHARDS

US Department of Health,
Education and Welfare,
National Institutes of Health,
National Institute of Allergy
and Infectious Diseases,
Laboratory of Parasitic Diseases,
Bethesda, Maryland 20014

A complex of several genetic factors determines the susceptibility of juvenile *Biomphalaria glabrata* to infection by *Schistosoma mansoni*. A simple dominant factor can cause juvenile susceptible snails to become refractory to the parasite at maturity. Stocks of such adults may prove to be of use in genetic control of *S. mansoni* in endemic areas.

LITTLE is known about molluscan genetics; studies are urgently needed in particular on the role of genetics in the transmission of diseases by molluscs and in molluscan systematics. The significance of genetics of insect vectors of disease has been demonstrated^{1,2}. We now report studies on the genetics of *Biomphalaria glabrata* (= *Australorbis glabratus*), intermediate host and vector of *Schistosoma mansoni* and a unique subject for molluscan genetic studies.

As indicated by geographic distribution, habitat range, and morphology, *B. glabrata* has remarkable variability³. It has a diploid chromosome number of 36 (ref. 4). Its generation time may be as short as a month⁵, and a snail may continue reproduction for more than a year. These snails are hermaphrodite and they can reproduce by self-fertilization through many generations, facilitating genetic selection. When two snails are mated, however, cross-fertilization usually dominates^{6,7}. Because suppression of self-fertilization is not always complete, the expression "post-cross" is used to distinguish a snail's progeny after mating from those before mating. Pigment markers were used to identify cross-fertilized individuals among the "post-cross" progeny.

Pigment Markers

Albinism is monofactorial and is recessive to wild type pigmentation⁸, and it has been used as a genetic marker

in systematic and other studies^{6,7,9-11}. A cross between a Brazilian albino and a Puerto Rican wild type pigmented snail produced the albino and wild type stocks in my laboratory¹². A laboratory mutant of this albino stock, "blackeye"¹³, has pigmented eyes and may have some black mantle pigment, but it lacks the black body and collar pigment which are characteristic of the wild type. Blackeye (*c^b*) is a third allele which is dominant over the albino (*c*) but recessive to wild type (*C*). (These pigment types were formerly referred to as *B*, *A*, and *C* respectively.) Selfing of a heterozygote such as *Cc* or *c^bc* (Fig. 1) consistently results in a 3:1 ratio showing that albinism is recessive and that reproduction is by self-fertilization, not parthenogenesis. When two such heterozygotes are mated, reciprocal cross-fertilization results in the post-cross phenotypic ratio 2:1:1 (*C:c^b:c*) from both snails. All blackeye progeny of the *Cc* parent are known to be the result of cross-fertilization, and all wild type progeny of the *c^bc* parent.

By selection and selfing through several generations, wild type and blackeye clones with and without black mantle spotting patterns were derived, including heterozygotes carrying the recessive albino genes. Mantle spotting seems to be a multifactorial character, but serves as a marker for one generation, spotted (*S*) being dominant over unspotted (*U*) (my unpublished work). Five pigment phenotypes (*c*, *c^bU*, *c^bS*, *CU*, *CS*) are now

available. Although unable to produce black pigment, the albino carries and transmits the mantle pigment pattern. This produces a 3-way cross as shown in Fig. 1. An albino from an unspotted stock can be mated with the other four pigment types, either in series or concurrently, and the "male" parent of each of the albino's offspring can then be identified. While most experimental matings involve one pair of individuals, in this case information could be obtained on reproduction in a natural population where the individual has the opportunity for promiscuous mating with several associates.

Tentacle and Eye Variation

Tentacle abnormalities have been observed in various snail species¹⁴⁻¹⁶. In *B. glabrata*, the tentacles are sometimes double, branched, bulbous or missing on either or both sides; and double, displaced or missing eyes are also found (Figs. 2 to 5) (my unpublished work). Tentacle and eye variation shows inheritance patterns similar to the tumorous head character in *Drosophila melanogaster*^{17,18}.

Pulmonary Cavity Occlusions

A hereditary structural aberration, a pulmonary cavity occlusion consists of a tissue mass in the parietal wall of the pulmonary cavity (Fig. 7). Selection and selfing resulted in clones in which frequencies of pulmonary cavity occlusions increased to as much as 70 per cent of a snail's progeny. Mating snails from such clones with normal stock snails results in post-cross F_1 progeny of both parents developing pulmonary cavity growths. In many cases the growths completely occlude the pulmonary cavity, preventing retraction of the snail into its shell.

Sublethal Characters

Another hereditary aberration consists of a median head bulb (Figs. 5, 6). Selection and isolated self-fertilization have shown inheritance of this, and in clones showing the head bulb snails which appear normal also transmit the character to their progeny. It is associated with a sublethal condition—egg clutches show about 20 per cent surviving snails, the other 80 per cent dying either in early cleavage or after abnormal development. The highest frequency of surviving progeny with the median head bulb was 30 per cent.

Spire formation is also associated with a sublethal effect (my unpublished work) (Figs. 8, 9). Spired snails were occasionally seen in colonies of *B. glabrata*. When isolated, they either failed to reproduce or produced only normal progeny. By observing developmental stages in egg clutches, however, we selected for consistent occurrence at a low frequency (10 per cent) of spire embryos. The egg clutches usually contain less than 50 per cent surviving infants, the remainder (including most of the spire embryos) dying in early cleavage or following abnormal development (Fig. 9). When we mated snails from such clones with stocks in which neither the spired snails nor the sublethal effect had been observed, post-cross progeny of both parents showed the characters.

Pearl Formation

Formation of spherical pearls (Fig. 10) of calcium carbonate in the extra-pallial fluid in depressions in the mantle was first noted in a clone of albino *B. glabrata*. Most of the

pearls are eventually incorporated in the shell. Selfing and mating studies indicate that pearl formation (prl) is inherited as a simple recessive factor, with absence of pearls (Prl) dominant (my unpublished work).

Polyembryony

Polyembryony has been reported for many snail species and is not uncommon in *B. glabrata*. The relationship of the multiple embryos is unknown in most cases, but "dizygotic twins"¹⁹ and "monozygotic conjoined embryos"²⁰ have been reported. Frequencies of polyembryony throughout various clones of *B. glabrata* indicate this is an inherited tendency. Observations on pigment marked heterozygous snails suggest that most of the multiple embryos in *B. glabrata* involve multiple zygotes in the same capsule.

Haemolymph Pigment

Snail haemolymph has been used in systematic and other studies²¹⁻²⁶. Intraspecific genetic variations in the chemical constitution of haemolymph are pertinent to such studies, and may also affect host-parasite relations. A marked increase in haemoglobin with growth from juveniles to adults has been reported²¹. By selection and selfing, we derived clones of *B. glabrata* showing variation in degree of red haemolymph pigment and in time of expression of such variation—both juveniles and adults with red haemolymph, juveniles deficient but adults with red pigment, and both juveniles and adults deficient. In some clones, snails with completely colourless blood occur consistently but in low frequency, but they rarely survive.

Susceptibility to Infection

A genetic basis for variations in susceptibility of *B. glabrata* to infection with *S. mansoni* has been proposed²⁷. Most reported studies on susceptibility have dealt with adults from interbreeding snail populations, from either the field or laboratory colonies.

In our studies on juvenile susceptibility, snails 1-4 mm in diameter were individually exposed to five miracidia of a Puerto Rican strain of *S. mansoni*. Each snail was examined 7-10 days after exposure and those in which developing sporocysts were not evident were again exposed

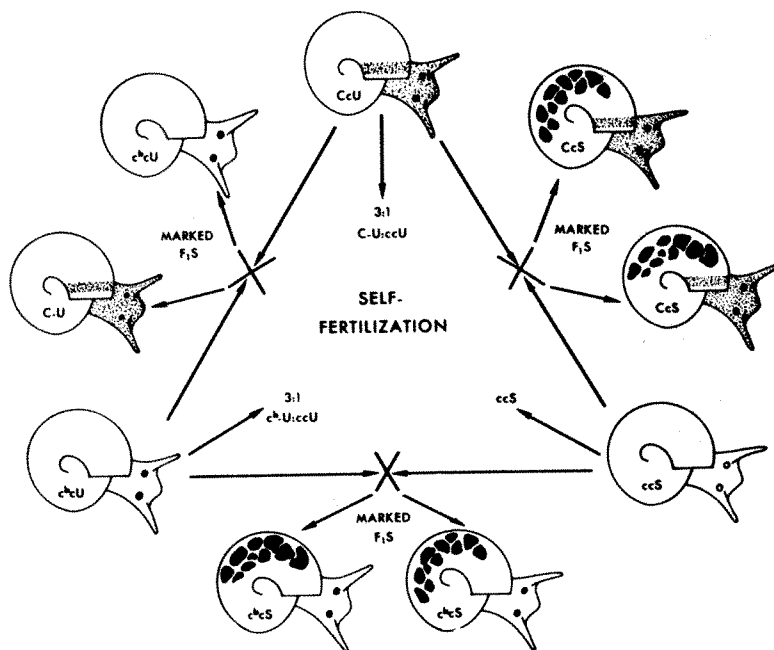

Fig. 1. Diagram illustrating: pigment markers in *B. glabrata*; wild type (C), blackeye (c^b), albino (c); spotted mantle (S), unspotted mantle (U); F₁ phenotypes qualitatively demonstrating cross-fertilization are depicted.

to five miracidia. Snails from a juvenile susceptible stock were used as controls with each exposure and re-exposure. Snails were checked for cercarial shedding at 6 weeks and at about 10 weeks. We considered infection as including any observed parasite development—primary sporocyst, secondary sporocyst or cercariae.

A cross was made first between a susceptible blackeye/albino heterozygote and a refractory homozygous wild type pigmented snail. Descendants of the susceptible parent by selfing produced progenies which were 90–100 per cent experimentally infected; post-cross F_1 s were 45 per cent infected. Descendants of the refractory parent by selfing produced progenies with 0 per cent infected; post-cross F_1 s 45 per cent infected. Several reported crosses between populations of “high” and “low” susceptibility have shown intermediate susceptibilities^{12, 28, 29}.

We isolated and selfed a series of forty F_1 s, twenty from each parent. Twenty-five of these F_1 s survived and produced progenies showing juvenile susceptibilities ranging from 0 per cent to 75 per cent. Stocks showing 100 per cent juvenile susceptibility and stocks showing no susceptibility were derived by selection and selfing through three generations. Genetic differences are not revealed so long as several susceptible clonal stocks are maintained by selfing, and tests show 100 per cent juvenile susceptibility. Tests on refractory clonal stocks showing no susceptibility also fail to demonstrate genetic variation. After selfing, a refractory wild type snail was mated as a male with ten albino or blackeye snails in series. Differences in susceptibility in cross-fertilized F_1 s of several susceptible albino mates suggested that these susceptible snails probably represented at least three different genotypes. When a blackeye refractory stock snail was used as a male in crosses with the same series of susceptible albinos, the susceptibility of cross-fertilized F_1 s differed from that of the refractory wild type parent, thus suggesting that the refractory stocks differed genetically. In matings between refractory snails from different stocks, some susceptible cross-fertilized F_1 s resulted, showing that refractory snails can carry susceptibility genes. From the many crosses conducted, I conclude that juvenile susceptibility is determined by a complex of several genetic factors.

In *B. glabrata* some snails susceptible as juveniles become refractory as adults^{21, 27}. Similar age effects have been reported for *Bulinus*³⁰ and lymnaeid snails³¹. The opposite effect, with susceptibility increasing with age, has been reported for some other planorbisid snails³². We exposed twenty-two adult snails descended from the susceptible refractory cross to twenty-five miracidia per snail. All proved to be refractory. We then isolated ten offspring from each of the snails derived from the above cross whose progenies showed high juvenile susceptibility (85 per cent–100 per cent). At the onset of egg-laying, thirty-one survivors were each exposed to twenty-five miracidia. All proved to be adult refractory. Control adults from the laboratory population became infected after exposure. Thirty-four offspring obtained by selfing from a juvenile susceptible stock snail were then exposed at various sizes. Thirteen offspring, less than 4 mm in diameter, were each exposed to five miracidia per snail. All became infected. Each of the remaining twenty-one offspring which had been reared in isolation was exposed to twenty-five miracidia after the first three had laid eggs at 10 mm diameter. One snail at 5 mm and two at 6 mm became infected, but none of the seven at 7 mm, four at 8 mm, four at 9 mm, or three at 10 mm became infected. These results suggest that “adult insusceptibility” in juvenile susceptible snails is initiated by developmental changes associated with maturation just before the onset of egg-laying.

Clonal stocks from two sibling albinos were followed through three generations by isolations and selfing. One

stock included both refractory and susceptible adults with the refractory snails predominating and with frequencies suggesting the presence of a single factor with susceptibility recessive. The other stock yielded 72/75 exposed adults susceptible, suggesting that these were homozygous recessive. In three crosses between juvenile susceptible/adult susceptible and juvenile susceptible/adult refractory snails, F_1 s produced 90–100 per cent juvenile susceptible, 0 (0/22) adult susceptible. F_2 progenies of seven isolated hybrid F_1 s showed 20 per cent (9/45) adult susceptible. These F_1 s were backcrossed to adult susceptible snails resulting in 52 per cent (25/48) backcross progeny which were adult susceptible. Additional crosses and isolations support the occurrence of a genetic factor with adult insusceptibility dominant and susceptibility recessive.

We now have three kinds of snail stocks with respect to developmental susceptibility to Puerto Rican *S. mansoni*: susceptible at any age, juvenile susceptible but adult refractory, and refractory at any age. On the basis of these preliminary results I postulate that a complex of several genetic factors determines juvenile (basic) susceptibility, insusceptibility being related to a deficiency of some requirement for parasite development; and that a simple, dominant factor (Mr) can cause juvenile susceptible snails to become refractory at maturity. There may be additional factors which modify the influence of this maturity factor. Implications of this inherited developmental variable in evaluating susceptibility either in the field or laboratory are obvious. In the epidemiology of schistosomiasis, only adult snails are usually considered but, as shown here, juvenile snails may be very significant. Infected juvenile *B. glabrata* have shed cercariae while only 1–8 mm in diameter.

Geographic variations involve the genetics of both host snail and trematode parasite^{27, 28, 33–35}. Preliminary observations have been made on host-parasite relations with five geographic strains of *S. mansoni* and eight different populations of *B. glabrata*. The *S. mansoni* strains which were tested fall into three groups on the basis of their infectivity; the snails into four groups on the basis of susceptibility. The results suggest that these differences in susceptibility of the snail may be related to variations in the requirements of the strains of the parasite.

Aestivation

Another physiological character is combined with morphological and behavioural features. Paraense described the occurrence of “apertural lamellae” (Fig. 11) and associated diapause in some small *B. glabrata* in Brazil³⁶ which had a tendency to climb spontaneously out of water and aestivate. I reported similar observations for *B. glabrata* in Puerto Rico³⁷. Physiological changes precede diapause, adapting these snails for prolonged aestivation³⁸. Lamella production and capacity for aestivation are inherited and genetically transmitted in cross-fertilization³⁹. Spontaneous aestivation provides insurance against unpredictable drought or chemical molluscicides⁴⁰. The efficiency of molluscicides would be affected by inheritance of avoidance behaviour or resistance⁴¹. A mutation in an aestivating *B. glabrata* has an excellent chance of survival, because at the end of the dry period the new population is started by only a few surviving snails⁴², and in some cases one isolated snail might repopulate a local habitat by self-fertilization.

Other Inherited Characters

The variations and aberrations described all occurred in a stock which has been under laboratory colonization for more than 15 years. We observed additional characters, the frequencies of which suggest inheritance: (1) Shell: colour amber or clear, high or low (umbilicus deep or shallow), multiplanar whorls (contorted shell), body whorl expanded. (2) Pigmentation: white pigment

granules of head and tentacles numerous or scarce; shape, size and distribution of mantle spots; kidney of newly hatched snails straw-coloured, magenta-coloured or blue to colourless; eyes of newly hatched snails red or black. (3) Egg clutches: contents of egg capsule clear, cloudy, with needle or flake-like inclusions, or with dendritic inclusions (Fig. 12); size, number and arrangement of egg capsules. (4) Growth: diameter at onset of egg-laying.

Genetic Control

Stocks of *B. glabrata* refractory to *S. mansoni* may prove of use in genetic control of this parasite, but it is essential to clarify the genetics of the factors involved and develop stocks carrying refractory characters only. Introduced into an endemic area, such stocks might be expected to hybridize with the local susceptible population resulting in a range of susceptibility combinations in succeeding generations, but transmission should be reduced. The presence of refractory *B. glabrata* in field populations should also have an effect on the miracidia⁴³ resulting in reduced infection frequency in the susceptible snails. If snails selected for a combination of insusceptibility and aestivation adaptation^{38,39,44} were introduced, a more rapid shift toward insusceptibility might be achieved following population reduction by drought or mollusciciding. Introduction of refractory snails would avoid the unpredictable hazard to the "balance of nature" of introducing new species (competitors, predators or parasites) in biological control.

I thank James W. Merritt for technical assistance, cooperation in planning and execution of procedures, and observations of frequently unpredictable results.

Lysolecithin and Cell Fusion

by

A. R. POOLE*

J. I. HOWELL

J. A. LUCY

Department of Biochemistry,
Royal Free Hospital School of Medicine,
University of London,
8 Hunter Street,
London WC1

Lysolecithin will induce cell fusion in several different types of cell, and both multinucleated syncytia and heterokaryons can be formed.

INTEREST in the fusion of biological membranes has recently been stimulated by investigations on the biochemistry of secretion¹, on the roles of membranes in the lysosomal vacuolar system² and, in particular, by work on the fusion of cells that is induced by viruses^{3,4}. For cell fusion induced by inactivated Sendai virus, it has been suggested that the virus provokes a general change in the plasma membrane of cells, which induces fusion as a secondary effect that no longer requires the presence of a virus⁵. More recently it has been shown, however, that the plasma membranes of Ehrlich ascites cells become degraded in contact with virus particles, and that this leads to the communication of the cytoplasm of adjacent cells through the breaks⁶. Other investigators have postulated that the Sendai virus contains a "cell wall destroying enzyme"⁷. Because phospholipase A com-

pletely abolishes the ability of Newcastle disease virus to cause cell fusion, it has been suggested that the phospholipids of the viral membrane are involved in the fusion process⁸. It has also been proposed that cellular lysosomal enzymes, rather than viral enzymes, are concerned in virus-induced cell fusion^{9,10}.

We now report experiments designed to test a working hypothesis for the fusion of biological membranes which is discussed in the following article¹¹. On this hypothesis, membrane fusion would be facilitated by factors, such as lysolecithin, that would be expected to favour a micellar organization for the lipids of biological membranes^{12,13}, rather than a bimolecular leaflet structure. We have therefore investigated whether lysolecithin can induce erythrocytes to fuse and form homokaryons: a brief report of cell fusion observed with hen erythrocytes has been published¹⁴. We have also studied the effects of

* Present address: Strangeways Research Laboratory, Cambridge.

lysolecithin on other blood cells and on LS fibroblasts. Several different cell types have been induced to fuse, and the formation of heterokaryons by inter-species fusion has been observed.

The lysolecithin used in the initial experiments was given by Dr G. R. Webster. It was prepared from ovoidlecithin with snake venom (*Agkistrodon p. piscivorus*), and was chromatographically pure (fatty acid composition: 67.2 per cent palmitic, 32.8 per cent stearic acid). A comparable preparation, supplied by Lipid Products (Epsom), gave similar results. Solutions of lysolecithin in 150 mM NaCl solution were prepared immediately before use. In some experiments siliconized glassware was used in the preparation of the solutions of lysolecithin: this procedure had no observable effect on fusion. The fibroblasts of the mouse strain LS cells, originally isolated by Professor J. Paul from the L (clone 929) strain, were derived from a culture provided by Professor S. J. Pirt. Bright-field and phase-contrast light microscopy were undertaken with a Vickers M26 inverted microscope, and electron microscopy was carried out with an AEI EM6b electron microscope.

Polysyncytium Formation

Hen erythrocytes, which were isolated and prepared for experimental work as described previously¹⁴, were rapidly lysed on treatment with lysolecithin. Light microscopy revealed that, before fusion, the ghosts tended to adhere to one another, sometimes in very large groups or chains. This observation is of considerable interest in relation to the factors governing cell adhesion¹⁵, and it indicates that one way in which adhesive cells may differ from non-adhesive cells could be in their relative content of membrane lysolecithin. Studies with the electron microscope showed that in some experiments many groups of cells had fused to form syncytia within 30 s of contact with lysolecithin. Part of such a syncytium is shown in Fig. 1 (page 813). A more magnified view of the apex of a large syncytium, where it is only one nucleus wide, clearly demonstrates cell fusion (Fig. 2). Neither fusion nor lysis occurred when erythrocytes were incubated for short periods at 37° C in buffer at pH 5.7 in the absence of lysolecithin. Some evidence of fusion was obtained with lysolecithin at pH 7, but a low pH was used in the experiments described here in an attempt to reduce electrostatic repulsion between cells. It may be relevant that the formation of giant cells in tissue cultures of chicken macrophages occurs most readily between pH 5.5 and 6.0 (ref. 16).

Membranes which were induced to fuse by treatment with lysolecithin were at the same time highly unstable. This instability frequently resulted in a complete breakdown of the multinucleate cells. In the experiment from which the electron micrographs of Figs. 1 and 2 were taken the syncytia, which were present after 30 s, rapidly disintegrated and were virtually absent in specimens fixed 3 min after the addition of lysolecithin. It may be significant that membrane disintegration, occurring 6–8 h after cell fusion, has been observed with syncytia formed both from sheep choroid plexus cells and from baby hamster kidney cells treated with visna virus particles¹⁷.

The precise sequence of morphological changes which occurs during fusion is of interest and preliminary findings suggest that the process may involve the formation of cytoplasmic bridges, as with cell fusion that is initiated by inactivated Sendai virus⁵. Other phenomena that we have observed with lysolecithin-treated erythrocytes include a loss of membrane rigidity, the formation of long, winding membranous processes derived from the plasma membrane, and the inclusion of closely packed membranes within the multinucleated syncytia. From observations on virus-induced cell fusion it has been concluded that, although the main mechanism of nuclear fusion involves post-mitotic reconstitution of several nuclei as a single large nucleus, interphase nuclei showing

varying degrees of fusion could also be seen in the virus-induced heterokaryons⁴. Fused nuclei were recognized in experiments with inactivated virus by their size, irregular shape and abnormally large number of nucleoli. In these studies with erythrocytes, nuclei of bizarre shape, but near normal size, were observed which may have been formed as a result of nuclear fusion following cell fusion. Ultrastructural work on the effects of lysolecithin on red cell morphology during cell fusion is being continued, and will be published elsewhere.

Avian erythrocytes are useful for studies on cell fusion. They are readily obtainable and, being nucleated, they make fusion easy to detect. In addition, because mature erythrocytes do not divide, there can be no confusion between fusing cells and dividing cells. Erythrocytes are nevertheless highly specialized, and it seemed possible that lysolecithin might not be able to induce the fusion of other cell types. That lysolecithin-induced fusion is not restricted to erythrocytes was initially shown, however, by the finding that heterophils are occasionally incorporated within the multinucleated syncytia that are formed when a preparation of erythrocytes contaminated with white blood cells is treated with lysolecithin¹⁴. Evidence that lysolecithin is able to cause fusion of various cell types has been provided by the following investigations.

Experiments were performed with exponentially grown mouse fibroblasts of the LS strain (grown in Eagle's minimum essential medium containing 10 per cent foetal calf serum)—these cells normally show relatively little adhesion to one another. Initially, treatment of the cells with lysolecithin (330 µg/ml.) in Hanks balanced saline solution led, even after only 30 s at 37° C, to membrane disruption in many of these cells. Attempts were then made to induce fusion of LS fibroblasts with one another by using sub-lytic quantities of lysolecithin. Occasionally clumps of apparently fused cells were seen with the light microscope, but these experiments met with little success: it seems that the membranes of the LS cells were more susceptible to lysis than to fusion under the conditions used.

Heterokaryons

In experiments on the formation of heterokaryons from LS fibroblasts and hen erythrocytes, the exponentially grown fibroblasts were washed twice in Hanks balanced saline solution, and resuspended in 150 mM NaCl just before use. Red cells were prepared as before¹⁴, and also resuspended in 150 mM NaCl solution before use. The two cell populations were mixed and added to an equal volume of 150 mM sodium acetate buffer (pH 5.6). Lysolecithin (dissolved in saline solution) was then immediately added. This treatment led to clumping and cell adhesion, observable by light microscopy. After 30 s at 37° C with lysolecithin, cell fusion had occurred and heterokaryons, as well as multinucleated erythrocytes, were seen with the electron microscope. These phenomena were not observed in control experiments without lysolecithin, although there was some evidence of cell damage that may have resulted from the low pH. Fig. 3 is a thin section of a portion of a multinucleated heterokaryon in which a fibroblast nucleus is closely associated with an erythrocyte nucleus. No plasma membranes can be distinguished between the nucleus of the fibroblast and the adjacent erythrocyte nucleus.

Another interesting example of heterokaryon production was observed when a preparation of hen mixed blood cells and LS fibroblasts was treated with lysolecithin. Fig. 4 shows part of a single LS fibroblast with which thrombocytes¹⁸ have fused at a number of different locations. The differing appearances of the cytoplasm of the two cell types can be seen better in Fig. 5, which also clearly demonstrates the absence of plasma membranes between the fibroblast and one of the thrombocytes. In addition to the heterokaryons illustrated here, hetero-

karyon formation has been observed with hen erythrocytes and mouse macrophages. The morphology of these heterokaryons resembles that of the hybrids formed from hen erythrocytes and LS fibroblasts.

In preliminary experiments on the stability of multinucleated cells produced by lysolecithin-induced fusion it has been found possible, by adding de-fatted serum albumin to the lysolecithin-treated cells, to arrest the associated degradative action of lysolecithin on cell membranes. Multinucleated cells can be obtained in this way which are apparently stable for several hours after the fusion process, as judged by light microscopy.

With regard to the proportion of cells undergoing fusion, it seems that this depends both on the concentration of lysolecithin and on the concentration of cells. Fusion was commonly seen in many experiments: the greatest incidence of fusion observed so far was in the experiment of Fig. 3, where electron microscopy indicated that about 20 per cent of the cells were involved in fusion.

Implications

These seem to be the first studies in which cell fusion has been induced, leading to the production of both multinucleated syncytia and heterokaryons, by treating cells with a simple chemical substance that is known to have a direct effect on the integrity of lipoprotein membranes. Fischer and his colleagues¹⁹ have previously noted, without comment, that fusion of cellular projections occurs in peritoneal macrophages treated with lysolecithin. Their light micrographs do not, however, enable a clear distinction to be made between fusion and adhesion.

The fusion of cell membranes caused by lysolecithin is consistent with the suggestion²⁰ that the ability of primary lysosomes to fuse with digestive vacuoles, and with the plasma membrane, may be due to lysosomal membranes containing a relatively high proportion of lysolecithin that results from the activities of lysosomal phospholipase A₁ or A₂ (refs. 21-23). Our findings also lend indirect support to the idea that lysolecithin may be concerned in the secretion of catecholamines from both normal and tumour chromaffin cells^{24,25}. In relation to secretions from tumour cells and the possibility that the invasive properties of malignant cells may involve extracellular release of lysosomal enzymes²⁶, it is interesting that some tumours contain a relatively high proportion of lysolecithin²⁷. The present observations also favour earlier suggestions that lysolecithin may participate in the release of histamine from mast cells²⁸ and in phagocytosis¹⁹. In addition, because there is circumstantial evidence that lysolecithin may be involved in demyelination²⁹, it may be pertinent to note that both demyelination and cell fusion have been reported with visna virus, canine distemper virus and mouse hepatitis virus¹⁷. It seems, however, that lysolecithin apparently does not participate in fusion of kidney cells by a para-influenza virus³⁰.

It could be argued that the lytic properties of lysolecithin, and the instability of lysolecithin-treated membranes preclude the idea of lysolecithin participating in membrane fusion occurring in living cells. We envisage, however, that in the latter situation lysolecithin may be produced at highly localized sites so that the overall integrity of the membranes concerned are not threatened *in vivo*, as they are when cells are treated with exogenous lysolecithin. It also seems likely that any cell fusion induced by lysolecithin *in vivo* may involve transient changes in the level of lysolecithin, and it may be significant that some cells can remove lysolecithin by two different reactions³¹, as well as producing it with phospholipase A. Together, the degradative and regenerating reactions provide a potential control system whereby the structures of membranes may be changed to allow fusion to occur as necessary. It has, indeed, been suggested previously that lysolecithin might be a precursor of lecithin in the pinching

off of plasma membranes and in the fusion of phagocytic vacuoles with the lysosomes of granulocytes³².

One important possibility is that heterokaryon production by means of lysolecithin treatment might provide a more controllable method for the formation of hybrid cells than the treatment of cells with viruses currently being used in studies on genetics, differentiation and cancer research. The technical manipulations involved in virus-induced fusion could be avoided in this way. Also there would be no possibility, with hybrids produced by lysolecithin treatment, of attributing the behaviour of the cells to the effects of viral components. Furthermore, should cell hybrids become of value in the treatment of human cancer by immunological techniques³³, hybrids prepared without the use of viruses would be of considerable clinical importance. Preliminary experiments in this laboratory on the viability of cells fused with lysolecithin indicate that the new technique may be adapted routinely for the production of hybrid cells.

The ability of lysolecithin to induce fusion in a number of different cell types leads us to consider its implication in the molecular mechanisms that are involved in other instances of membrane fusion. Because lysolecithin-induced fusion is predictable from the hypothesis discussed in the following article¹¹, our observations seem also to support the possibility that the formation of micelles of lipid or lipoprotein within membranes, under the influence of a variety of appropriate agents, may be a general mechanism for the fusion of biological membranes.

Fig. 1. Electron micrograph of a section through part of a large syncytium formed from hen erythrocytes in which nineteen nuclei can be distinguished. Erythrocytes were prepared and treated with lysolecithin as previously described¹⁴. The incubation mixture (1.7 ml.) contained 4×10^8 hen blood cells and 560 μg of lysolecithin in 106 mM NaCl and 44 mM sodium acetate buffer: final pH 5.7. After 30 s at 37° C with lysolecithin, the cells were fixed by the addition of ice-cold glutaraldehyde and they were then prepared for electron microscopy as before¹⁴.

Fig. 2. A section of part of a syncytium in which hen erythrocytes have fused lengthwise to form a chain of nuclei enclosed within a single plasma membrane. The outer surface of the membrane, stained by ruthenium red, is clearly observable (arrows). Reproduced with permission from ref. 14.

Fig. 3. An electron micrograph of part of a heterokaryon containing the nucleus of a hen erythrocyte (E) and the nucleus of a mouse LS fibroblast (F). The incubation mixture (1.3 ml.) contained 4×10^8 hen blood cells, 2.8×10^6 mouse LS fibroblasts and 240 μg lysolecithin in 92 mM NaCl and 58 mM sodium acetate buffer: final pH 5.7. Cells were fixed with ice-cold glutaraldehyde after 30 s at 37° C with lysolecithin.

Fig. 4. A low magnification electron micrograph of a mouse LS fibroblast (F) that has fused with a number of surrounding hen blood thrombocytes (T). The incubation mixture (1.7 ml.) contained 2.6×10^8 hen blood cells, 2.5×10^6 mouse LS fibroblasts and 560 μg lysolecithin in 106 mM NaCl and 44 mM sodium acetate buffer: final pH 5.7. The preparation was fixed with glutaraldehyde as in previous experiments.

Fig. 5. A detail of the syncytium of Fig. 4, showing region of fusion between a thrombocyte (T) and fibroblast (F) at higher magnification (arrow).

Fig. 1. Cross-sectional view of a membrane in which globular micelles of lipid are in dynamic equilibrium with a bimolecular leaflet of lipid⁴. A layer of protein and/or glycoprotein is shown on each side of the lipid layer. The structure of each lipid molecule is illustrated in diagrammatic fashion: only a polar head group and a non-polar moiety are shown, and the lipid may be phospholipid or non-phospholipid. One globular micelle of lipid has been replaced by a globular protein molecule (*Pr*) which may be a functional enzyme. (Reproduced from the *British Medical Bulletin*⁵ with the permission of the British Council.)

Fig. 2. This is intended to illustrate diagrammatically the possible involvement of micellar configurations of lipid molecules in the fusion of membranes. Stage 1: diagrammatic illustration of a cross-sectional view of the lipid molecules of parts of two adjacent membranes. In the upper membrane, the lipids are wholly in the form of a bimolecular leaflet. The lipids of the lower membrane are organized partly in a bimolecular leaflet and partly in globular micelles: specific, endogenous molecules, which may be either lipid (represented by ● with tail) or protein, are responsible for the stability of the globular micelles in the lower of the two membranes. It is postulated that fusion between two membranes will not occur if either (or both) of two adjacent membranes has its lipid molecules predominantly in the form of a bimolecular leaflet. Stage 2: as a result of the presence of an exogenous perturbing molecule, which may be either lipid (illustrated by ■ with a tail) or protein, a transition has occurred in the organization of the molecules of the upper of the two membranes. This membrane now resembles the lower membrane (as shown here) in having localized areas in which its lipids are organized in globular micelles. Stage 3: interdigitation of the globular micelles of the two adjacent membranes leads to a local fusion of the membranes into a single entity. Stage 4: breakdown of the unstable coalesced membrane-junction may simultaneously create and eliminate membrane-bound compartments. Stage 5: a final stage in membrane fusion may be the reversion of one or both membranes (as shown here) to the bimolecular leaflet form as a consequence of metabolic transformations involving one or more of the chemical components of the membranes. (In the context of pinocytosis, both the upper and lower membranes of stage 2 are considered to be part of the same plasma membrane. The molecules represented by ● and ■ with tails are to be regarded as identical in pinocytosis and also in cell fusion.) Stages 1-4 are reproduced from ref. 15 with permission of the North-Holland Publishing Co.

Fig. 3. A diagrammatic illustration (stage 3) of one way in which lysolecithin (● with tail) may interact with lipoprotein membranes, and cause membrane fusion by inducing changes in the organization of both the lipid and protein moieties of the two membranes. The presence of the lysolecithin may lead to the formation of globular micelles of lipoprotein which facilitate fusion. This figure was drawn by Mr R. A. Parker.

The Fusion of Biological Membranes

by

J. A. LUCY

Department of Biochemistry,
Royal Free Hospital School of Medicine,
University of London,
8 Hunter Street, London, W.C.1.

A working hypothesis for the fusion of membranes is discussed. It is suggested that the process may involve phase changes in the lipids of membranes with the formation of micellar units of lipid or lipoprotein.

ALTHOUGH much is known of the structure and function of individual biological membranes, knowledge of the processes concerned in the fusion of membranes, a phenomenon so important in biology and medicine¹, is limited. Fusion in the lysosomal vacuolar system has recently been discussed in terms of "exoplasmic" and "endoplasmic" space by De Duve² and by Dingle³, who has suggested that membrane-bound vesicles will fuse only at a high value of surface tension. I now wish to draw attention to relationships between the structures of membranes and some of the factors that induce membrane fusion, and discuss relevant aspects of examples of membrane fusion. A possible molecular mechanism for the fusion of membranes is put forward on the basis of an earlier suggestion that the lipids of membranes may be arranged in globular micelles in appropriate circumstances instead of in a bimolecular leaflet^{4,5} (Fig. 1). Observations on the fusion of cells treated with lysolecithin, which are thought to be consistent with this mechanism, are reported in the preceding article⁶.

Phase Changes within Membranes

Okada *et al.*⁷ have proposed that cell fusion by Sendai virus involves first a virus-induced disconnection of the original plasma membranes, and then the connexion of membranes between adjacent cells. Any mechanism for membrane fusion which involves the physical removal or destruction of parts of adjacent membranes, however, seems unable to account for the fact that simple leakage of proteins, enzymes and subcellular organelles does not normally accompany membrane fusion. Thus disconnection of membranes is unlikely to be involved in the initial stages of the fusion reaction. Rather it seems more probable that a change occurs in structural organization which allows the altered membranes to participate in the fusion process and also to retain some degree of structural integrity.

Although membrane proteins are without doubt of great structural and functional importance, phospholipid molecules seem, nevertheless, to be a *sine qua non* for the formation of membranes in biological systems. I therefore suggest that the configuration of the lipid molecules of membranes is of primary importance in the process of membrane fusion, and that fusion will occur only if the lipid molecules are appropriately orientated. It is also proposed that the reorganization of membrane structure which occurs during fusion involves a phase-change in membrane lipids. This does not imply that the conformation of membrane proteins has no influence on the orientation of the lipid molecules. Indeed, membrane proteins and glycoproteins are probably principal factors in determining whether or not the lipids can adopt a configuration that will allow membrane fusion to occur. The stability and properties of bimolecular

lipid leaflets in aqueous solution have been examined theoretically by Haydon and Taylor⁸. They concluded that transitions from a bimolecular leaflet to aggregates of radially orientated molecules will occur if phospholipid molecules having a net charge, or wedge-shaped phospholipids, or non-phospholipid molecules, are introduced into the lipid leaflet. When dispersions of lecithin and cholesterol in water were investigated by the negative staining technique of electron microscopy, both spherulites and tubular structures were observed⁹, each tube apparently being made up of five parallel rows of globular lipid micelles having measurable (hydrophobic) diameters of about 40 Å. Although specific factors, such as the negative stain, may conceivably be responsible for the presence of globular micelles of phospholipid in such dispersions¹⁰, it is quite possible that conditions leading to the formation and stabilization of globular micelles may occur within biological membranes *in vivo*. The influence of various biochemical and physiological factors on this equilibrium, and the possibility that the proportion of micellar configuration might normally be very low, were stressed when the existence of globular micelles in membranes was initially considered⁴. Recently Danielli¹¹ has also commented that the important question is not whether the membrane has a specific structure (for example, bilayer or micelle), but rather how much of the membrane is present at one time in a particular structure or conformation, and how changes in these ratios are controlled by the cell. Stein¹² has suggested that the globular micelle may be the most stable arrangement for lipid molecules at the front of an advancing myelin figure, in view of the known change in birefringence which occurs at the ends of myelin forms. Observations made by the technique of freeze-etching led Branton¹³ to propose that most biological membranes are organized in part as bilayers of lipid and in part as globular subunits.

Globular Lipid Micelles and Membrane Fusion

Thermodynamic considerations indicate that the bimolecular leaflet is probably the natural unit of structure for lipid membranes^{8,14}, and the stability and lack of coalescence that biological membranes normally exhibit could well be a reflexion of the importance of the bilayer structure in these membranes. Membrane fusion may not occur if the lipids of one (or both) of the membranes concerned are almost entirely in the bimolecular leaflet configuration. Conversely, it is suggested that the primary requirement for the fusion of two membranes is that both of the membranes have a relatively high proportion of their phospholipid molecules in the micellar configuration. Any situation which favours the micellar organization rather than the bilayer should therefore tend to facilitate membrane fusion, although changes in the bilayer-micellar equilibrium may, of course, be second-

ary to a primary change that does not affect membrane lipids directly.

This hypothesis is illustrated diagrammatically in Fig. 2 (page 814) for the lipid molecules of two membranes which, in stage 1, show no tendency to fuse (Fig. 2:1). One of these membranes may be regarded as a plasma membrane that is relatively free from micelles. The other may be considered as part of a cytoplasmic organelle, for example, a primary lysosome which may normally have a relatively high proportion of micelles in its membrane¹⁵. Stage 2: any agent that increases the proportion of micelles in the plasma membrane (Fig. 2:2) might facilitate membrane fusion, for, if two apposed membranes both contain micelles, fusion may occur by interdigitation of the micelles as illustrated in Fig. 2:3. The arrangement depicted in Fig. 2:3, stage 3, could be described as a coalesced state of membranes. But whereas thermal motion and cytoplasmic streaming may allow the temporary formation of such a coalesced structure, these same factors will limit the lifetime of this complex junction of membranes. On breakdown of the junction, the membranes may either revert to the initial structures from which the junction was formed, or they may break up in the way illustrated in Fig. 2:4. In the latter instance, stage 4, area *W* (representing, for example, the interior of a secretory organelle) is brought into direct contact with area *X* (representing the exterior of the cell).

A final stage in membrane fusion may be the reversion of the structures of the membranes concerned to the bimolecular leaflet configuration. In some instances, reversion might not occur. In others it may be slow—old endocytotic vacuoles fuse less readily than newly formed vacuoles³, and a slow change in the structure of vacuole membranes may occur as the organelles move through the cytoplasm. By contrast, a relatively rapid reversion to the bimolecular leaflet structure probably follows the fusion of cells induced by viruses. Such a change may be necessary in order to confer stability on the resulting multinucleate cells. It is envisaged that the effects of the perturbing molecules which initiate the fusion process may be neutralized in stage 5 as a result of metabolic reactions, thus allowing the membrane lipids to revert to the more stable bimolecular leaflet configuration. This could, presumably, be achieved in many ways, depending on the perturbing molecule or molecules involved. For example, with cell fusion induced by lysolecithin⁶, the effective removal of lysolecithin by its conversion to lecithin would enable the membrane lipids to reform virtually continuous bimolecular leaflets in stage 5.

Although these diagrams illustrate a relatively simple situation in which the transition from a bimolecular leaflet to a micellar configuration results from the incorporation of perturbing molecules into the lipids of the membrane, I anticipate that different kinds of perturbing molecule will produce comparable changes in the organization of membranes by differing mechanisms. Some of these may involve interactions not only with the proteins but also with the glycoproteins of membranes. (The diagrams of Fig. 2 are necessarily a gross simplification.)

Any comprehensive molecular mechanism for membrane fusion must also take into account the known energy requirements for fusion. Although the discharge of zymogen granules is independent of protein synthesis, the process nevertheless uses respiratory energy¹⁶. Formation of very small liposomes by prolonged ultrasonic dispersion of lecithin in water, and the production of microsomal vesicles from the endoplasmic reticulum by homogenization, may result from the pinching-off of membranes and not simply from the linking of the ends of ruptured fragments. Should this be so, the applied sonic or mechanical energy may be responsible for the occurrence of transient phase changes in the membrane lipids which facilitate membrane fusion. Energy may

also be needed in stage 5 of the fusion process. Respiratory energy is apparently required for the fusion of Ehrlich ascites cells by Sendai virus. This may be related to the stability of the membranes of newly formed polykaryocytes, for cell lysis occurred instead of cell fusion when 2,4-dinitrophenol was added before incubation of the cells with virus at 37° C (ref. 7). Control cells were not lysed by dinitrophenol. On the present hypothesis, these observations may be interpreted in terms of cell fusion occurring up to and including stage 4 but with lysis occurring in the presence of dinitrophenol as a result of a failure of metabolism to convert extensive areas of micellar configuration back to the bimolecular leaflet form in stage 5. Should cell fusion induced by Sendai virus involve lysolecithin, the requirement for respiratory energy may be for the acylation of lysolecithin to lecithin in stage 5. This reaction, which occurs in intact and lysed erythrocytes, requires coenzyme A and ATP¹⁷.

Lysolecithin

Lysolecithin constitutes one of the simplest agents that would be expected to facilitate membrane fusion. As a consequence of its wedge shape, the incorporation of lysolecithin into a bilayer should produce a transition from a bimolecular leaflet to radially orientated molecules⁸. When lysolecithin is dispersed in water it forms globular micelles¹⁸ and the effectiveness with which lysolecithin micellizes membrane lipids¹⁹ is probably responsible for the lytic properties of this molecule.

Lysolecithin will induce cell fusion and heterokaryons can be produced by the use of lysolecithin⁶. It is unlikely, however, that lysolecithin causes membrane fusion solely by an effect on membrane lipids. Lysolecithin seems also to interact with the proteins of membranes. It has been reported that treatment of myelin with lysolecithin yields a complex protein-lipid-lysolecithin micelle²⁰. Nuclear magnetic resonance studies of erythrocyte membranes co-dispersed with lysolecithin also indicate that lysolecithin forms an additive complex with membrane material²¹, and work with optical methods suggests that treatment of plasma membranes with lysolecithin or with phospholipase A results in changes in the structure of membrane proteins²². In the light of these findings, the simple diagram of Fig. 2:3 may be modified to indicate a possible role for membrane proteins in the fusion of cells that is induced by lysolecithin (see Fig. 3).

Vitamin A Alcohol

Retinol resembles lysolecithin in behaving as a surface-active agent^{23,24}. It causes leakage of enzymes from isolated lysosomes *in vitro*²⁵ and the loss of haemoglobin and potassium from erythrocytes²⁶. Retinol would be expected to decrease the stability of a bimolecular leaflet of phospholipid⁸, so that it has been proposed that the lytic actions of retinol arise from the presence of a high proportion of globular lipid micelles in membranes that contain an excess of retinol⁴. On the present hypothesis, retinol (like lysolecithin) should cause membrane fusion, and experiments are being undertaken in this laboratory to see if retinol will cause cell fusion and the formation of syncytia. It has already been demonstrated, however, that treatment of erythrocytes with retinol leads to invagination of the cell membrane, followed by the formation of internal vacuoles by a process morphologically resembling pinocytosis²⁷. The membrane fusion that is involved in this process may be depicted by Fig. 2:2 if both of the membranes in this figure are regarded as micellar portions of the infolded plasma membrane of the cell. Interdigitation of the micelles (Fig. 2:3) would lead to the separation of the interior of the newly-formed vacuole *Z* from the exterior of the cell *Y*. With retinol, formation of internal membrane-bound vacuoles is associated with a general increase in the permeability

MACACA MULATTA**Enzyme Histochemistry of the Nervous System**

by **SOHAN L. MANOCHA** and **TOTADA R. SHANTHA**, both at the Neurohistochemistry Laboratory, Yerkes Regional Primate Research Center, Department of Anaesthesiology, Emory University, Atlanta, Georgia.

A comprehensive examination of the nervous system of the rhesus monkey from anatomical, cytoarchitectural, and histochemical viewpoints. The book describes the various nuclei and important fibre systems of the brain, spinal cord, olfactory bulb, eye and peripheral nerves with regard to their anatomical location, cellular composition and relationship to surrounding structures. August 1970, 362 pp., £10.05 (\$21.50)

A New Journal...

THEORETICAL POPULATION BIOLOGY

AN INTERNATIONAL JOURNAL

Edited by **J. F. CROW**, Department of Genetics, University of Wisconsin, Madison, Wisconsin, **N. KEYFITZ**, Department of Demography, University of California, Berkeley, California, **S. KARLIN**, Department of Mathematics, Stanford University, Stanford, California, **R. MacARTHUR**, Department of Biology, Princeton University, Princeton, New Jersey.

Managing Editor: **J. McGREGOR**, Department of Mathematics, Stanford University, Stanford, California.

Today, population biology is the subject of increasing interest and concern. A central source of information is a must for researchers in this field. Questions of planning population structure from the genetic to the demographic level have become ever more crucial in the adequate analysis and creation of environments. This new interdisciplinary journal will publish papers on the theoretical aspects of the biology of population, especially in the areas of ecology, genetics, demography and epidemiology emphasizing the development of the theory.

Volume 1, 1970 (3 issues) £6 13s. 4d. (\$16.00)
(Add 13s 4d (\$1.60) for postage outside U.S.A. and Canada)

Personal Subscription £4 3s. 4d. (\$10.00)
(Add 13s 4d (\$1.60) for postage outside U.S.A. and Canada.)

CELLULAR MECHANISMS OF CHROMOSOME DISTRIBUTION

Supplement 2 to *International Review of Cytology*

by **PETER LUYKX**, Laboratory for Quantitative Biology, University of Miami, Coral Gables, Florida.

September 1970, 173 pp., in preparation.

THE MAMMALIAN MITOCHONDRIAL RESPIRATORY CHAIN

by **WALTER W. WAINIO**, Department of Biochemistry, Rutgers, The State University of New Jersey, New Brunswick, New Jersey.

This volume presents a concise review of the ever-increasing knowledge of the mammalian mitochondrial respiratory chain. The book discusses mitochondria from liver, heart, brain, and kidney, emphasizing such aspects as mitochondrial structure and composition, energy conserving mechanisms, and the components of the chain-dehydrogenases, cytochromes, nonheme iron, and ubiquinone. September 1970, about 450 pp., in preparation.

A New Journal...

CELLULAR IMMUNOLOGY

AN INTERNATIONAL JOURNAL

Volume I

Editor-in-Chief: **H. SHERWOOD LAWRENCE**

Cellular Immunology provides an international medium devoted exclusively to publication of original investigations concerned with the immunological activities of cells in experimental or clinical situations. The scope of the journal encompasses the broad area of *in vitro* and *in vivo* studies of cellular immune responses. These include, for example, delayed type hypersensitivity or cellular immunity; immunologic surveillance and tumour immunity, transplantation immunology, autoimmunity, resistance to intracellular microbial and viral infection; immunologic deficiency states and their reconstitution; antigen receptor sites; thymus and lymphocyte immunobiology, etc. 1970 (6 issues) £14.00 (\$30.00). (Please add 12s. 6d. (\$1.50) postage outside U.S.A. and Canada.)

CELLS AND TISSUES BY LIGHT AND ELECTRON MICROSCOPY Volume 2:

Systems and Perspectives in Morphology

by **EDMUND B. SANDBORN**, Département d'Anatomie, Faculté de Médecine, Université de Montréal.

Translated into French by **REAL GAGNON**, **PIERRE JEAN**, **BERNARD MESSIER**

August 1970, 379 pp., 138s. (\$15.00)

MEDICAL VIROLOGY

by **FRANK FENNER**, John Curtin School of Medical Research, Australian National University, Canberra, A.C.T., Australia, and **DAVID O. WHITE**, School of Microbiology, University of Melbourne, Melbourne, Victoria, Australia.

September 1970, about 380 pp., in preparation.

GORDON AND BREACH SCIENCE PUBLISHERS

RADIATION EFFECTS

Editor: Lewis T. Chadderton, Science Center
Thousand Oaks, California

This successful monthly journal brings together original works dealing with radiation. Radiation Effects publishes experimental and theoretical papers of both fundamental and applied nature. Topics included range from the physics of the effects of radiation on crystalline materials, through radiation chemistry, metallurgy, biology and biochemistry, to biophysical effects in the 'life' molecules and 'in vivo' physiological studies.

Radiation Effects is pleased to announce the publication of papers from three important conferences.

EUROPEAN CONFERENCE ON ION IMPLANTATION

to be held from Sept. 7-9, 1970, at the University of Reading. The purpose of this conference is to provide a forum for the discussion of all aspects of the physics and technology of ion implantation. Leading workers in the field are presenting review papers on a wide range of subjects.

NONMETALLIC CRYSTALS: the International Conference on the Science and Technology of Nonmetallic Crystals held at New Delhi in January 1969. The proceedings collect together a wealth of important new information relating to semiconductor and organic crystals.

RADIATION EFFECTS IN SEMICONDUCTORS to be held from Aug. 24-26, 1970, at the State University of New York at Albany. The purpose of this conference is to consider the basic science (theory and experiment) of phenomena associated with defects in the elemental semiconductors and the compound semiconductors and the related phenomena such as ion implantation, channeling etc.

Papers from these conferences will be published shortly in Radiation Effects.

Prices per volume:

Great Britain (Libraries) £15.10.0
(Individuals) £5.0.0

USA/Elsewhere (Libraries) \$41.00/£17.1.6
(Individuals) \$13.50/£5.12.6

FERROELECTRICS

Editors: I. Lefkowitz, Pitman Dunn Research
Laboratory

G. W. Taylor, RCA Laboratories

This new quarterly international journal which is now in its third issue is designed to provide a forum for people working in ferroelectrics and related materials such as electrooptics, piezoelectrics, pyroelectrics, and liquid crystals. Ferroelectrics publishes experimental and theoretical papers aimed at the understanding of ferroelectricity and associated phenomena and applied papers dealing with the utilization of these materials in devices and systems.

Prices:

Great Britain (Libraries) £20.16.6
(Individuals) £5.10.0

USA/Elsewhere (Libraries) \$53.00/£22.1.6
(Individuals) \$14.50/£6.0.0

Charter Offer

We are pleased to offer a special discount of 33 $\frac{1}{3}$ % per volume to libraries and individuals who enter a 3-volume charter subscription to this journal in its first volume of publication. In addition 3-volume charter subscribers are offered a 10% discount on future 1-volume renewals. 3-volume charter subscribers may pay their subscription all at once or volume by volume.

Charter Subscription Rates:

Great Britain (Libraries) £13.17.8
(Individuals) £3.13.4

USA/Elsewhere (Libraries) \$36.00/£15.0.0
(Individuals) \$9.70/£4.0.0

Your profile interests us.

Our computer matches your profile of interests to each week's journal articles.

ASCA® (Automatic Subject Citation Alert) is a custom information service geared to your personal information needs. For technical administrators and working scientists it is an insurance policy—insurance that you won't miss any item of specific interest appearing in over 2,500 scientific or technical journals.

No longer need you depend upon hit-or-miss browsing to locate current information that is valuable to your work. (Including material published in obscure or foreign journals to which you don't subscribe.) For ASCA gives you massive, comprehensive coverage on a totally selective basis.

It gives you what's *pertinent*.

How does ASCA work? You simply complete a profile specifying the topics in which you're interested. We then alert you each week to all articles that fall within the precise areas of interest defined by you. We also provide an easy way to obtain the articles you want quickly and inexpensively.

Now in its fourth generation, ASCA has reached a high level of sophistication. It allows you to pinpoint with remarkable accuracy and efficiency—as no other service can—information relevant to your work.

How do you write a profile? By asking individual questions or combinations of questions. Including cited reference questions, an ISI exclusive.

Here are some examples of the types of questions you may include in your profile. You can ask for all items in current journals that cite the work of a particular author . . . all articles citing a particular journal or a particular work . . . everything a particular author or organization publishes . . . all titles containing a single word, a word fragment or a combination of words. Even Boolean expressions may be used. And you can add, or delete, questions at any time.

In short, ASCA is a must for anyone concerned with science. And it's remarkably inexpensive considering the coverage and personalized nature of the service. Economical

group plans are also available.

Want to know more about ASCA? Just return the coupon below.

Spin-Temperature and Nuclear Magnetic Resonance in Solids MAURICE GOLDMAN

**OXFORD
UNIVERSITY
PRESS**

The book presents a unified description of the high-temperature approximation for spin-temperature theory, and of its chief applications to nuclear magnetic resonance in solids. Emphasis is put throughout on the twofold character of the theory: first as a branch of thermodynamics that exploits systematically the consequences of the fundamental hypothesis of the existence of a temperature within a spin system; and secondly as a practical tool that widens the possibilities of the use of nuclear magnetic resonance for the study of solid-state physics. 'MICHIROME'

STAINS & REAGENTS FOR BIOLOGY

Acridine orange, Aquamount, Fluormount, Lipid crimson, Matamount May-Grünwald, Leishman, Giemsa Toluidine blue, Cresyl fast violet Papanicolaou stains, Thioflavine S, Brilliant cresyl blue, Nile blue Pyronin Y, Trifalgaic acid, Rhodanile blue, Haplo, etc.

CATALOGUE AVAILABLE ON REQUEST

DYES FOR USE IN ALL INDUSTRIES

RESEARCH & PRODUCTION CHEMISTS: if you are seeking dyes with specific chemical and physical properties suitable for particular manufacturing and/or testing processes you are invited to contact us for supplies.

We hold stocks of an enormous variety of dyes, ready for immediate despatch, including:

Cyanine, Dicyanine, Fast Bordeaux O, Aurantia, Crystal violet, BPC-Scarlet R, BPC, Diazonium salts, Neutral violet, Lacmoid, Nile blue, Janus green, Brilliant green BPC, Rosolic acid, Methyl green, p-Ethoxy-chrysoidin, Methyl red, Nitrazine yellow, Pinacryptol green, etc.

INDUSTRIAL RESEARCH ESTABLISHMENTS

are invited to make use of our professional services as consultants on the selection and use of dyes as research and production tools.

of the plasma membrane and subsequent cell lysis. By contrast, agents such as polyamino-acids, which induce pinocytosis apparently without increasing membrane permeability²⁸, may facilitate a transition to the micellar configuration at fewer more localized sites by specific interactions with membrane proteins.

In living chondrocytes, vitamin A facilitates the fusion of some form of lysosome—possibly enzyme-containing Golgi vesicles—with the plasma membrane. Retinol causes an extracellular release of lysosomal enzymes from skeletal tissue in organ culture, and this leads to a degradation of the extracellular matrix of cartilage rudiments^{29,30}. There is no biochemical or cytological evidence of cellular damage when this occurs, and it seems unlikely that large quantities of lysosomal enzymes are freely released within the cells. This action of retinol may perhaps be explained by proposing that it forms lipid micelles in the plasma membrane, and facilitates the fusion of lysosomal membranes (that may already contain micelles because of the presence of lysolecithin) with the plasma membrane (see Fig. 2). A similar mechanism may conceivably apply to the fusion of primary lysosomes with the plasma membrane by complement-sufficient antiserum, which causes a specific synthesis and release of lysosomal hydrolases into the extracellular environment without the apparent release of lysosomal enzymes within the cell³¹. Complement-sufficient antiserum seems to have no effect on isolated lysosomes^{32,33}.

General Considerations

Many biological phenomena involve membrane fusion, including fertilization, cell division, extracellular secretory processes, endocytosis, the formation of secondary lysosomes, the extracellular release of enveloped viruses, and cell fusion occurring *in vitro* or *in vivo* either as a result of a virus infection, or spontaneously, to yield heterokaryons or normal multinucleated cells such as myotubes. Some general mechanism for membrane fusion may apply, with variations in individual systems, to all these processes. The mechanism proposed here for membrane fusion is too rudimentary to warrant an extended discussion of its possible application to these various phenomena, but it is interesting to consider certain features of secretion in the present context. Fusion of subcellular organelles with the plasma membrane seems, in many cases, to be the result of a complex sequence of events. Thus a number of stages are distinguishable in the glucose-stimulated secretion of insulin, and glucose does not cause the direct release of insulin from isolated secretory granules³⁴. By contrast, pinocytic vacuoles commonly fuse with one another to form larger vacuolar structures^{35,36}. Some secretory organelles, for example, chromaffin³⁷ and zymogen granules³⁸, are capable of fusing with one another. Secretory granules in the anterior pituitary gland also fuse with lysosomes when extracellular secretion is suppressed³⁹. Thus while fusion of organelles with the plasma membrane seems to depend on the occurrence of an induced change in the structure of the plasma membrane, the observed inter-organellar fusion of secretory and digestive vesicles may indicate the existence of a common structural organization in the membranes of these organelles which facilitates fusion.

Factors inhibiting membrane fusion, although not considered in detail here, may be regarded as of equal importance to those facilitating fusion. It is noteworthy that high concentrations of calcium inhibit the extrusion of lysosomal enzymes from leucocidin-treated leucocytes⁴⁰. Degranulation of leucocytes is particularly interesting, for the inhibition of degranulation produced by high levels of calcium may possibly arise from an inhibition of micelle formation, which could result from cross-linking by divalent calcium ions of adjacent phospholipid molecules in a lipid bilayer¹⁴. Another agent known to stabilize membranes is cortisol. Attention has previously

been drawn¹⁵ to the fact that the action of retinol in producing both instability in individual membranes and facilitating membrane fusion is matched by a similar parallelism for cortisol, which stabilizes membranes and inhibits membrane fusion.

In summary, I suggest that the interaction and intermixing of the lipids of membranes which occur during fusion require the lipid molecules of both membranes to be appropriately organized; and further, that agents capable of causing membrane fusion do so by inducing—directly or indirectly—a phase change in the lipids of one or both of the membranes concerned. For fusion to occur a relatively high proportion of the lipids of both membranes may need to be organized in micelles of lipid or lipoprotein. Interdigitation of the micelles of the two membranes could then lead to membrane fusion. On this hypothesis, any structural, metabolic or energetic factor that acts on the lipid, protein or glycoprotein moieties of membranes and favours the micellar configuration in local areas should facilitate the fusion of membranes at these sites. Certain agents such as lysolecithin would therefore be predicted to induce fusion, and support for the proposed mechanism is provided by experiments in which lysolecithin has been observed to cause cell fusion⁶. This working hypothesis may be of value in future experimental studies, particularly those on the control mechanisms involved in fusion in biological systems.

X-ray Photographs of the Sun on March 7, 1970

by

L. P. VanSPEYBROECK

A. S. KRIEGER

G. S. VAIANA

American Science and Engineering,
Cambridge, Massachusetts

The Sun was photographed from an Aerobee rocket by means of equipment responding to the wavelength interval 3–60 Å, revealing interesting relationships between structures in the corona.

DURING the eclipse of March 7, 1970, we obtained X-ray photographs of the Sun with an Aerobee rocket payload. The photographs were taken at the end of the partial eclipse as seen from White Sands, New Mexico. X-rays in the wavelength region of sensitivity of our telescope (3–60 Å) are emitted essentially only at temperatures higher than 10^6 K. The X-ray images therefore show the solar corona without interference from the radiation of the cooler photosphere and chromosphere, and coronal structures on the disk as well as at the limb can be studied.

The purpose of this preliminary article is to present a morphological description of the X-ray corona of March 7 and to relate the X-ray observations to the white light observations of the limb¹ and to the observations of the photospheric magnetic field² on March 7. This preliminary discussion is limited to the large scale X-ray structures and their most evident associations with the magnetic field and the white light corona. The quantitative analysis of the X-ray photographs, their spectral content, and the detailed association of the X-ray emission with the magnetic field structures and with the structures seen at other wavelengths, will be treated in later articles.

In previous papers^{3–5} we have stressed the importance of the photospheric magnetic field in determining the three-dimensional structure above the active regions. This new set of photographs also demonstrates the magnetic field to be the governing agent for the structure of the X-ray emission outside the active regions. In particular: (1) We establish the presence in the corona, as seen in X-rays, of a "complex of activity" and relate it to the definition of Bumba and Howard⁶. (2) We establish the presence at coronal heights of the interconnection of the preceding polarities of active regions across the solar equator as originally postulated by Babcock⁷. (3) We identify certain diffuse components of the X-ray corona outside active regions with old remnants of former active regions and relate them to the unipolar magnetic regions of Bumba and Howard and their "ghosts", and therefore to the bases of the white light rays and helmet streamers. (4) We recognize several components in the X-ray emission of a plage including a small bright component located in regions of large longitudinal field gradient which is similar in appearance to X-ray flare features that we have observed in previous flights.

Instrumentation and Data

The X-ray telescope is very similar to the one flown over the past several years and described in detail in the literature^{4,5,8}. It consists essentially of a grazing incidence X-ray mirror, a camera in the focal plane, a sequence of filters transmitting specific broadbands in the 3–60 Å wavelength region, a pointing control system and appropriate control electronics. Three years of minor but important improvements in the instrumentation (particularly in the areas of filters, camera and electronic controls) have led to higher sensitivity for the longer wavelength X-rays which are produced primarily by the cooler coronal plasma. Faint structures in the corona outside active regions which would have been unobservable in previous flights are therefore visible in these photographs. These results clarify the association of the X-ray corona with chromospheric features and the white light corona.

The data consist of a series of exposures with various passband filters and exposure times (Table 1).

Exposure No.	Duration* (s)	Nominal passband†
1–62	1.5	P, 3–30 Å, 44–55 Å
63	49	P, 3–30 Å, 44–55 Å
64	29	M, 3–15 Å, 44–48 Å
65	27	T, 3–13 Å, 19–24 Å
66	11	P, 3–30 Å, 44–55 Å
67	6	T, 3–13 Å, 19–24 Å
68	6	M, 3–15 Å, 44–48 Å
69	7	B, 3–15 Å
70	1	White light

* The exposures were taken between 1854.28 and 1858.54 UT.

† The filter materials are as follows: P = 0.85 µm 'Parylene N' + 2500 Å Al; M = 3.8 µm 'Mylar' + 3000 Å Al; T = 3.2 µm Teflon + 1.1 µm 'Parylene N' + 3000 Å Al; B = 1.3 µm Be + 1000 Å Al. The nominal passbands correspond to 5 per cent or greater transmission.

Description of Photographs

The general appearance of the X-ray corona is similar to that observed in our previous experiments^{3–5}, but the higher sensitivity at longer wavelengths (due to filters of greater transmission) results in a more complete view of the various coronal X-ray structures and of their relation to the photospheric magnetic field, and the chromospheric features.

Figs. 1a and b (exposures 66 and 65 of Table 1) show the X-ray corona in different wavelength passbands. The combination of passbands and exposure times is such that Fig. 1a shows the more diffuse component of the corona while Fig. 1b shows structures within the active regions. The limb of the Moon is evident near the east limb of the Sun. Diffuse X-ray emission, often having a loop-like appearance, covers the disk intensely in the regions of the activity belts and weakly in the polar regions. The limb brightened X-ray emission around the Sun is not uniform and local regions of enhanced X-ray emission and gaps of reduced emission are present. This is most noticeable in the north and south polar regions where there is less interference from the emission of active regions on or near the limb. Near the active regions, close to the limb, there are structures looping above the active regions and arching from one active region to another. This is particularly noticeable in the complex of active regions at the west limb, where structures link McMath regions 10621, 10602, 10604, 10595 and 10598 (an identification of the corresponding CaK plages is given in Fig. 2). The features on the north central portion of the disk would presumably have a similar appearance if observed at the limb. In Fig. 1b the X-ray structure of the active regions is evident. Most X-ray plages contain one or more bright, narrow cores, typically 10 to 20 arc seconds in length and having a striated appearance with apparent width comparable with the resolution of the X-ray telescope (3 to 5 arc seconds). These are particularly noticeable in regions 10618A, 10618B, 10618C, 10618D, 10614, 10617 and 10607 (see Fig. 2). A more extended emission involving the overall plage and revealing its three-dimensional structure is seen superimposed on the bright cores.

Fig. 1c is a composite of the exposure shown in Fig. 1a and the white light corona as photographed during the eclipse by Newkirk and Lacey¹ of the High Altitude Observatory. There is a detailed correspondence between various features on the X-ray exposure and white light coronal structures. At the limb, the X-ray brightenings noted in Fig. 1a mark the bases of the white light coronal features. Table 2 describes the relationship between the white light and X-ray appearance of some of the more notable coronal features.

Fig. 1. The appearance of the corona in X-rays and white light on March 7, 1970. *a*, An X-ray exposure in the bands 3–30 Å, 44–55 Å; *b*, an exposure in the band 3–13 Å, 19–24 Å; *c*, a superposition of the X-ray exposure of *a* and the white light coronal photograph taken by Newkirk and Lacey¹.

Fig. 3. Comparison of X-ray emitting structures as photographed in three passbands: (a) 3-30 Å, 44-45 Å; (b) 3-15 Å, 44-48 Å; (c) 3-13 Å, 19-24 Å; and (d) the corresponding photospheric magnetic field, measured by Livingston *et al.*⁵

Fig. 4. A region of diffuse X-ray emission on the disk as observed on November 4, 1969, in (a) soft X-rays, (b) photospheric magnetic fields, (c) H α , and (d) CaK. The photospheric magnetic field measurements were provided by Mount Wilson Observatory; the H α and CaK photographs were provided by Sacramento Park Observatory.

Table 2. RELATIONSHIP OF WHITE LIGHT AND X-RAY FEATURES

Position angle (measured east from solar north)	Remarks
50°	The large helmet streamer observed in white light cannot be regarded as an extension of the X-ray structure above the core of region 10617. We therefore infer that this streamer must be associated with the filament and large scale active region remnants to the east. The relationship between region 10617 and these remnants is clearly shown by the magnetogram of March 12, 1970, obtained by Livingston <i>et al.</i> ²
80°	The bright enhancement at the X-ray limb corresponds to a coronal white light feature. We attribute these features to region 10623, east of the limb on March 7.
98°	The enhancements at the X-ray limb and the associated white light helmet streamer are not connected to region 10618, but originate behind the limb probably in region 10624 or related remnants.
140°-175°	There is a one to one correspondence between the bright limb X-ray enhancements and the brighter regions at the base of the assembly of white light streamers.
180°	A gap in the bright X-ray limb corresponds to the inter-streamer region visible in white light.
194°	The white light helmet streamer is not associated with any front disk X-ray feature. X-ray enhancements are again apparent at the bases of the streamer. The streamer is probably associated with the remnants of region 10584 on the other side of the Sun as conjectured by Teske <i>et al.</i> ³
215°-240°	A large gap appears in the bright X-ray limb associated with the white light features of much lower intensity in this region. Faint X-ray emission from the limb is evident near the middle of this gap on the original negatives however.
250°	A complex X-ray structure is evident on the limb inter-connecting regions 10621, 10602 and 10604. The general shape of this structure corresponds to the shape of the lowest portions of the white light streamer.
292°	The bright "horn" in white light is associated with X-ray emission corresponding to regions 10595 and 10598 behind the west limb. The X-ray structures also indicate a connexion to region 10604 to the south which may explain the nonradial appearance of the white light structure.
330°-30°	As in the south-east, there is an excellent correspondence between brightness enhancements on the X-ray limb and the bases of the white light rays.

In Fig. 3, enlargements of a section of the disk, photographs in different wavelength passbands, are compared in detail with the magnetic field. Fig. 3a is the exposure shown in Fig. 1a. Fig. 3b is a 29 s exposure in the nominal passbands 3 to 15 Å and 44 to 48 Å. Fig. 3c corresponds to Fig. 1b and Fig. 3d is part of the magnetogram of Livingston *et al.*². There is an evident relationship between the coronal structures observed in soft X-rays and the underlying photospheric magnetic field. The diffuse X-ray emitting regions running north-south in Fig. 3a connect regions of preceding magnetic polarity across the solar equator. Both the general X-ray plage structure, seen best in Fig. 3b, and the bright X-ray plage cores of Fig. 3c seem to take the form of tubes linking the preceding and following magnetic polarity portions of the active regions. The bright, narrow tubes appear where the gradient of the longitudinal photospheric magnetic field is highest and connect adjacent regions of opposite polarity. The larger, dimmer tubes follow more curving paths and connect more widely separated regions.

Interpretation of Results

From the general appearance of the X-ray corona on the disk we observe that large sections of the solar atmosphere encompassing many active regions and remnants of older regions are interconnected by emitting loops filled with plasma. From the comparison with the magnetic field maps of Livingston *et al.*² and the definition and discussion of Bumba and Howard⁶, it is apparent that they are the coronal configurations corresponding to their "complex of activity". The best example shown in Fig. 1a includes active regions 10614, 10618A, 10618B, 10617 and 10619. Notice the lack of emission separating this complex from the other complex including 10606, 10607, 10608 and 10610; in H α this separation is marked by an old filament.

The active regions imbedded in a "complex of activity" show a general X-ray structure, seen best in Fig. 3b,

which often seems to take the form of tubes linking the preceding and following magnetic polarity portions of the active regions. Often active regions are "mixed" in the sense that a considerable portion of the magnetic flux of a following polarity is linked to a preceding polarity portion of another active region. The sharing of flux between 10618A, B and C in Fig. 3a is a clear example of this. When seen close to the limb these active region structures occupy the cores of hot coronal condensations and young streamers as seen in white light (see in Fig. 1c the regions on the west limb and the regions corresponding to plage 10623).

Within this general X-ray structure most active regions contain very bright structures, often striated and tubular in appearance, linking the preceding and following magnetic polarity of the region across the neutral line of the longitudinal field at points where the gradient of the longitudinal field appears to be particularly high. The positional association with the neutral longitudinal field line, where many flares are known to occur, and the fact that the flare we observed on June 8, 1968, had a bright hot kernel associated with one such feature suggest that the small bright active region structures play an important part in the X-ray flare. The data are also consistent with a continuous distribution of loop configurations in which the vertical scale of a structure reflects the horizontal separation of the connected regions, and structures linking widely separated regions are higher, less dense and therefore weakly emitting, whereas the structures connecting adjacent regions of opposite polarity are lower, more dense, and therefore strongly emitting.

Among the diffuse emission linking active regions in a "complex of activity" we find several examples of X-ray emission showing magnetic flux going from preceding polarities on one hemisphere to preceding polarities on the other hemisphere. A good example is shown in Fig. 3a where the preceding polarity portion of regions 10618A and B connect to remnants of opposite polarity in the north and toward the preceding portion of 10617. This coronal configuration is consistent with a "severing and reconnection of lines of force" of the type required by the Babcock model of the solar cycle⁷.

We have previously^{3,4} pointed out the presence of weak X-ray emitting regions associated with the brighter portions of the calcium network pattern. We have also argued from the similarity of the spectra of the X-ray corona seen at the limb and of the diffuse emission on the disk that these are two views of the same object. A series of four rocket flights by our group over the past three years have (1) confirmed the existence of the diffuse component; (2) shown that these structures are more diffuse than the calcium network although they often have a feather-like appearance at our resolution; (3) identified the brightest diffuse structures, if not all of them, with remnants of old active regions of the type giving rise to unipolar magnetic regions and their "ghosts"⁸; and (4) related them to enhancements at the X-ray limb. A good example of these enhanced diffuse emissions on the disk is shown in the X-ray photographs taken on November 4, 1969, with similar instrumentation. Figs. 4a, b, c and d show the appearance of the south polar region in X-rays, magnetic field, H α and CaK respectively. Notice the filament separating the regions of opposite polarity and the corresponding gap of emission in the X-ray photograph.

The eclipse X-ray observations and their correlation with the white light corona permit us to associate the feet of coronal rays and helmet streamers with X-ray enhancements at the limb (Fig. 1c). This, together with our previous observations, allows the association of X-ray diffuse structures on the disk with streamers and rays. This is in agreement with the evolutionary classification of helmet streamers by Newkirk¹⁰ (based on the inferred association of prominences and migrating magnetic regions) and with our interpretation of the diffuse X-ray

enhancements on the disk with old remnants of active regions.

We thank the National Aeronautics and Space Administration and the White Sands Missile Range, particularly the Navy Aerobee group, for help and support. Dr John Davis, Mr Robert Haggerty, Mr William Hamilton, Mr Heinz Manko, Mr David Webb, and many other members of our organization made essential contributions. We also thank Dr G. Newkirk and Dr W. Livingston for results before publication.

Interstellar Silicate Absorption Bands

by

J. A. HACKWELL

University College, London,
and University of Minnesota, Minneapolis

R. D. GEHRZ

N. J. WOOLF

University of Minnesota,
Minneapolis, Minnesota

Interstellar silicate absorption is observed in the direction of the galactic centre. Most interstellar silicon seems to be in silicate form.

SILICATES have two absorption bands near 10 μm and 20 μm . Fig. 1 from Lyon¹ shows the absorption spectrum of enstatite ($\text{Mg}_{0.5}\text{Fe}_{0.5}\text{SiO}_3$), a typical meteoritic mineral. Because Knacke, Gaustad, Gillett and Stein² had apparently observed a 10 μm interstellar absorption in the M21b supergiant 119 Tauri, we looked for more heavily reddened objects in which the absorption should appear in medium bandwidth photometry. Unfortunately the brightest reddened objects at these wavelengths, M supergiants, have large unpredictable infrared emission where the absorption feature should appear.

Reddened B stars might provide a more predictable continuum, and so three B stars with about four times the colour excess of 119 Tauri were observed. A four-colour photometer was used with the Kitt Peak 50 inch metal mirror telescope. The photometric equipment constructed and assembled by Drs Gillett and Stein provided passbands at 3.8, 4.8, 8.5 and 11.5 μm effective wavelength. At 3.8 μm we have allowed for atmospheric water vapour in assessing the effective wavelength.

The two longest wavelength passbands can be compared with Fig. 1, where it is seen that silicates have little absorption at 8.5 μm , but peak absorption near 11.5 μm . The observations of the stars are reported in Table 1, together with visual observations by Hiltner³.

First we note that for unreddened stars of type near AO, all magnitudes should be approximately the same. Unfortunately the difference between the 8.5 μm and 11.5 μm magnitudes for the first two stars is about equal to the uncertainty in these differences. In HD 168625, the elevated continuum suggests that the star is a Be star, and uncertainties about the shape of the continuum prevent these observations from being used. Clearly, reddened B stars are both rather faint for this study and also have unpredictable continua.

Dr F. J. Low has suggested (personal communication) that the galactic centre provided a bright continuum in the 10 μm region while suffering severe visual interstellar absorption. Further, he commented that his

Fig. 1. Absorption spectrum of enstatite ($\text{Mg}_{0.5}\text{Fe}_{0.5}\text{SiO}_3$).

photometric measures⁴ appeared to indicate spectral structure in the 10–20 μm region.

Four-colour photometric measures were then also made for the galactic centre by R. D. G. and N. J. W. The 10 inch diameter photometer beam was centred on the source by peaking the signal observed at 11.5 μm . Atmospheric absorption corrections were made by observing α Sco at the same air mass. This star is well tied to our photometric system, and the shape of the 10 μm continuum is also known from spectral scans. The results for two separate nights of observation are shown in Table 2.

Table 2. PHOTOMETRIC OBSERVATIONS OF THE GALACTIC CENTRE WITH 10" BEAM

Night	Scale	3.8 μm	4.8 μm	8.5 μm	11.5 μm
June 23, 1970	Magnitude	+5.04	+3.01	-0.91	-1.94
June 24, 1970		+4.19	+2.04	-1.19	-2.02
June 23, 1970	Flux units	3.1	12.6	150	210
June 24, 1970		6.8	30.6	195	224

It is believed that the short wavelength discrepancies between the two nights are caused by slightly different centring of the beam, combined with the wavelength-dependent source structure and telescope diffraction. At 3 μm Becklin and Neugebauer⁵ have shown that a

Table 1. PHOTOMETRIC OBSERVATIONS OF REDDENED B STARS

Star	Type	V	3.8 μm	4.8 μm	8.5 μm	11.5 μm	$\Delta(\text{B}-\text{V})$	$\Delta(\text{V}-8.5)$
HD 183143	B7Ia	+6.87	+3.22	+3.11	+2.73	+2.95	1.29	4.14
168607	B9I*ap	+8.29	+3.15	+2.42	+2.56	+2.77	1.60	5.73
168625	B8Ia+*	+8.41	+3.82	+3.01	+1.80	+1.14	1.48	6.81

* $\text{H}\beta$ is suspected to be in emission in this star, noted in HD catalogue.

point source dominates the energy output while at $10\ \mu\text{m}$ the core has an angular extent of 15 inches, slightly displaced from the point source. If either set of measures are plotted as magnitude against $1/\lambda$, the 11.5 points seem to fall below a smooth continuum by ~ 0.5 .

A better measure of the depth of the interstellar feature can be obtained by combining the present observations with those of Low *et al.* Fig. 2 shows the two sets of observations normalized to a common beam size by assuming that all fluxes measured by Low *et al.* have the same angular distribution as the $11.5\ \mu\text{m}$ flux. If a smooth continuum is drawn, there seem to be two absorption features with a similar wavelength distribution to Fig. 1. The central optical depth of the band at $10\ \mu\text{m}$ is $\tau \approx 0.7$. Gaustad⁶ has tabulated the absorption coefficient of enstatite, and the observations would require $3 \times 10^{-4}\ \text{g cm}^{-2}$ of silicate to produce the observed absorption. The visual absorption of the galactic centre is 25 ± 5 magnitudes, thus there seems to be $1.2 \times 10^{-5}\ \text{g cm}^{-2}$ of silicate per magnitude of visual absorption. At a typical galactic plane absorption of $2\ \text{mag kpc}^{-1}$ and interstellar hydrogen density of $1\ \text{atom cm}^{-3}$, silicates would form 0.4 per cent by mass of the interstellar medium. For typical cosmic abundances, this is the maximum amount of silicate that could form, being limited by the cosmic silicon abundance.

The star 119 Tauri suffers ~ 1.5 of visual absorption, and thus by comparison with the galactic centre one would expect a central depth of the $10\ \mu\text{m}$ feature of only 4 per cent, which is undetectable with present accuracy. Other doubts about this observation have also arisen⁷. The spectrum of 119 Tauri was therefore observed at Kitt Peak by J. A. H. and N. J. W. The spectrometer was identical with that used at Lick Observatory for the earlier observations. A method of rapid scanning was used, and after 8 h of observation and 178 scans, the results seemed to show a significant discrepancy with the earlier measures in that the $9.6\ \mu\text{m}$ feature did not appear, Fig. 3. Despite the inadequate extent of the spectrum to short wavelengths, however, the SiO double feature at $8.1\ \mu\text{m}$ centre does appear. There is a possible wavelength discrepancy of

Fig. 2. Photometric measures of the galactic centre. ●, Low *et al.*; +, night 1; x, night 2.

Fig. 3. Spectrum of 119 Tauri (M2Ib). □, Hackwell; ○, Knacke *et al.*

$0.1\ \mu\text{m}$ between the two observations, and because greater care was paid to this point in the earlier observations, this should not be regarded as a significant difference. The difference in absolute calibration, however, is significant and is perhaps related to the different energy distributions derived in the two observations.

It seems that the earlier results may have suffered from inadequate correction for ozone absorption. Large telescopes are extremely efficient for spectral studies, as the observing time required is proportional to (diameter)⁻⁴; however, because of limited access to large optical telescopes, there has been a tendency to spend most time observing faint sources, and insufficient observing time has been spent tying down atmospheric corrections. One of us (N. J. W.) assisted in the planning and execution of some of the earlier observations of 119 Tauri.

In contrast to the discrepancy between the galactic centre observations and 119 Tauri earlier observations, the observations of the reddened B stars are consistent with the galactic centre observations. The stars HD183143 and HD168607 would be expected to show a deficiency of $11.5\ \mu\text{m}$ over $8.5\ \mu\text{m}$ by $+0.16$. The agreement with the observed value $+0.23$ is much better than the observational error would predict.

In the agreement with expectations aroused when silicates were identified in the Orion Nebula^{8,9}, this material is abundant in interstellar space. The abundance seems to be limited by the cosmic silicon abundance. The absorption spectrum seems to be typical of terrestrial silicates and not anomalous as might have been inferred by a premature report of its discovery.

We thank Dr G. Neugebauer for providing a finding chart for the galactic centre. Generous provision of observing time by Kitt Peak National Observatory made these observations possible. J. A. H. is supported by a special grant from the Science Research Council of Great Britain; R. D. G. is a US National Science Foundation trainee. This research was supported by funds from NASA and by the Graduate School, University of Minnesota.

Direct Method of Measuring Stratospheric Water Vapour Mixing Ratios

THE measurement of the mixing ratio, μ , of water vapour to air in the stratosphere has been carried out many times, using spectroscopic methods, from both aircraft^{1,2} and balloons³⁻⁶. As a result of the range of values that have been obtained the subject has become controversial^{6,7}. We present here some submillimetre wavelength measurements made in an aircraft observing atmospheric emission, using methods of Fourier transform spectrometry⁸, which may provide an improved method of obtaining this parameter. Previous submillimetre atmospheric emission measurements⁹ have produced estimates of stratospheric water content, but the quantitative value of these results is limited because of the problem of radiometrically calibrating the system in order to obtain reliable measures of background and zero levels. In the present work the direct comparison of water vapour and oxygen emission has largely removed these requirements and greatly simplified the analysis.

The observations were made flying in a Comet 2E of Radio Flight, RAE, Farnborough, England, on November 14, 1969, at an altitude of 12.2 km, with an ambient temperature of 222 K (at 2.8 km above the tropopause, temperature 215 K). (These data were supplied by the Meteorological Office, Bracknell, Berkshire.) A Michelson interferometer and a 350 mm diameter Cassegrain telescope were mounted at an angle of 10° above the horizontal to view the atmosphere through a four-aperture, 16 mm thick, polypropylene window. The submillimetre radiation exchange passing between the Golay cell detector and the atmosphere was phase-modulated (J. Chamberlain, unpublished) in the interferometer, amplified, synchronously rectified, and the output signal digitally recorded after smoothing with a 1 s time constant electronic filter. The greatly improved performance

Fig. 1. Phase modulated interferogram function obtained at an altitude of 12.2 km.

Fig. 2. Example of observed atmospheric emission used to estimate the water vapour mixing ratio μ . The crosses are the computed spectral points and the dashed lines show the measured emission areas. (Average of two spectra; altitude 12.2 km; resolution 0.5 cm⁻¹.)

gained by phase-modulation (J. Chamberlain, unpublished) resulted in interferograms with a signal to noise ratio about 40 (Fig. 1) and, from these, good quality transformed spectra over the range 20 to 65 cm⁻¹ were obtained to a resolution limit of 0.5 cm⁻¹ in an observation time of 30 min. At this resolution limit a large number of atmospheric features can be identified, and the analysis of these, together with a complete discussion of experimental details, will be published later. Here we concentrate on the features assigned to water vapour and oxygen and, in particular, pairs of comparable intensity and separated by only a small frequency interval (< 2 cm⁻¹). An example of two such lines, occurring in the 25–26 cm⁻¹ region, is shown in Fig. 2. These features can be used to make a direct measurement of the mixing ratio of water vapour and oxygen, and hence of water vapour to air (μ) with knowledge of the oxygen to air mixing ratio.

The computation of the mixing ratio μ is possible if it can be assumed that over the emission path the water vapour to oxygen mixing ratio is constant and the temperature of the region is approximately constant. Then if the emission lines are "strong" (that is, with an emissivity of the order of unity in the region of line-centre), the ratio of the integrated emission-strengths (E) of the two lines can be shown to be given by¹⁰

$$\left(\frac{E_{\text{H}_2\text{O}}}{E_{\text{O}_2}}\right) = \left(\frac{S_1 \Delta\sigma_1 p_1}{S_2 \Delta\sigma_2 p_2}\right)^{\frac{1}{2}}$$

so that

$$\frac{p_1}{p_2} = \left(\frac{E_{\text{H}_2\text{O}}}{E_{\text{O}_2}}\right)^2 \times \frac{S_2 \Delta\sigma_2}{S_1 \Delta\sigma_1} \quad (1)$$

where p_1 , p_2 are the mean pressures of water vapour and oxygen (atm); S_1 , S_2 are the line strengths of the two lines (cm⁻² atm⁻¹); and $\Delta\sigma_1$, $\Delta\sigma_2$ are the line widths of the two lines (cm⁻¹). Now the mass mixing ratio μ is related to equation 1 by

$$\mu = \frac{p_1}{p_2} \times \frac{M_1}{M_2} \times \frac{k_2}{k_0} \quad (2)$$

where M_1 and M_2 are the molecular weights of water vapour and oxygen; and k_2 and k_0 are the mean con-

centrations of oxygen and air in g m^{-3} over the emission path; so that, in units of g/g ,

$$\mu = \left(\frac{E_{\text{H}_2\text{O}}}{E_{\text{O}_2}} \right)^2 \times \frac{S_2 \Delta\sigma_2}{S_1 \Delta\sigma_1} \times \frac{M_1 k_2}{M_2 k_0} \quad (3)$$

Thus in order to derive μ only $[E_{\text{H}_2\text{O}}/E_{\text{O}_2}]^2$ has to be measured experimentally, the other terms either being well established (M_1 , M_2 , k_2 and k_0) or theoretically evaluated for specific lines (S_1 , S_2 , $\Delta\sigma_1$ and $\Delta\sigma_2$) (refs. 11–14). In the case of line parameters, experimental work in the millimetre and submillimetre region has provided support for the theoretical calculations and shown that systematic errors in theory of $\Delta\sigma_1$ and $\Delta\sigma_2$ tend to be reduced using the ratio $(\Delta\sigma_1/\Delta\sigma_2)$ (refs. 15–18). Using this technique, a value of $\mu = 2.0 \times 10^{-6} \text{ g/g}$ was obtained for the pair of lines shown in Fig. 2, and a mean value for all the lines accessible in the range 20 to 65 cm^{-1} (that is, clearly resolved pairs of oxygen and water vapour lines of comparable intensity and not affected by other atmospheric constituents such as ozone) was

$$\mu = (2.1 \pm 0.3) \times 10^{-6} \text{ g/g}$$

The quoted errors are the r.m.s. deviation of the values of μ measured, and thus provide a measure of the possible accuracy of the experimental technique, but no allowance has been made for the systematic errors that may be present either in the line parameters or in the analysis. This value of the stratospheric mixing ratio is in good agreement with other results for the dry stratosphere model^{1,2}. The effect of water vapour in the optical path (about 1 m) in the aircraft was less than 5 per cent of emission from the atmosphere and can thus be considered negligible in this experiment.

This result applies to the lower stratosphere only; the energy of emission in the "strong" lines used decreases away from the observer, falling to $1/e$ in a distance corresponding to a vertical height of about 3 or 4 km above the aircraft. The measurement of weak emission lines will yield information about higher altitudes, and these are being investigated in the more detailed analysis of the present results to be published later.

The value of this method of measuring the stratospheric mixing ratio μ may be summarized by considering the following points.

(a) The relative strengths of the strong electric dipole transitions of water vapour (approximately $2 \text{ cm}^{-2} \text{ atm}^{-1}$) and the weak magnetic dipole transitions of oxygen (approximately $1 \times 10^{-5} \text{ cm}^{-2} \text{ atm}^{-1}$) are particularly suited to measuring water vapour to air mixing ratios in the range 10^{-6} to 10^{-5} g/g , which are encountered in the stratosphere.

(b) The existence of a considerable number of oxygen transitions in the submillimetre region which can be resolved from nearby water vapour lines enables increased accuracy to be obtained by measuring several sets of features. Further, the multiplicity of both strong and weak water vapour lines which are available for consideration will probably allow an extension of the analysis to include more complex distributions of water vapour in the stratosphere².

(c) In balloon work, though not of such importance in aircraft work (see above), the use of atmospheric emission enables long path lengths to be considered, and consequently reduces the problem of local contamination caused by water vapour outgassing from the apparatus.

Finally, the combination of the inherent advantages of Fourier transform spectrometry in the submillimetre region, the more complete information of the parameters of the rotation lines of water vapour and oxygen, and the elimination of the need for guidance equipment (a requirement for comparable solar studies) in atmospheric emission measurements seem to recommend this technique strongly for future studies of the mixing ratio in the stratosphere.

We thank members of the Radio Department, RAE, Farnborough, for help throughout this work, in particular Mr N. D. P. Hughes, Mrs S. P. Jenkins and Mr F. Mayhead.

The Classical Charged Photon

BONNOR^{1,2} has given a solution of Maxwell's equations which can be interpreted as a radiative field caused by a source moving at the speed of light. Because the world-line of the source is therefore a null curve Γ , the current four-vector J^i is everywhere tangent to it. Hence

$$g_{ik} J^i J^k = 0 \quad (1)$$

where g_{ik} is the metric tensor in local coordinates. In Bonnor's solution L^i is always parallel to J^i , that is

$$J^i = Q L^i \quad (2)$$

where Q is a scalar field. It will be shown below that in Minkowski space, for a null (or radiative) solution of Maxwell's equations satisfying equations (1) and (2) only, the radiation is propagated along a family of null straight lines which is, in general, shear-free, expanding and twisting. Further, in the absence of twisting, Q in these solutions vanished at every point of Γ . Bonnor's rather strange solution arises as the singular solution of equation (10) below, which gives zero expansion and twist.

Now, radiation problems in space-times can be discussed very conveniently in terms of tetrads of null-vectors (L^i , N^i , M^i , \bar{M}^i), where L^i and N^i are real, M^i and \bar{M}^i are complex conjugates

$$\begin{aligned} L^i L_i = 0, \quad N^i N_i = 0, \quad M^i M_i = 0, \quad \bar{M}^i \bar{M}_i = 0, \\ L^i N_i = 1, \quad M^i \bar{M}_i = -1 \end{aligned} \quad (3)$$

and all remaining scalar products vanish³. (I write $\pi = -N_{ik} \bar{M}^i L^k$ to avoid confusion with the transcendental real number π .) Instead of coordinate derivatives $\partial/\partial x^i$ and Christoffel symbols it is more convenient to use the linear differential operators

$$D = L^i \frac{\partial}{\partial x^i}, \quad \Delta = N^i \frac{\partial}{\partial x^i}, \quad \delta = M^i \frac{\partial}{\partial x^i}, \quad \bar{\delta} = \bar{M}^i \frac{\partial}{\partial x^i} \quad (4)$$

and the Newman-Penrose spin coefficients $\alpha, \beta, \gamma, \varepsilon, \kappa, \lambda, \mu, \nu, \pi, \rho, \sigma, \tau$ respectively³. The Maxwell equations with source

$$J^i = i^1 L^i + i^2 N^i + i^3 \bar{M}^i + i^4 \bar{M}^i \quad (5)$$

become

$$\begin{aligned} D\varphi_i - \bar{\delta}\varphi_0 &= (\pi - 2\alpha)\varphi_0 + 2\rho\varphi_1 - \kappa\varphi_2 + \frac{2\pi}{c}i^2 \\ D\varphi_2 - \bar{\delta}\varphi_1 &= -\lambda\varphi_0 + 2\pi\varphi_1 + (\rho - 2\varepsilon)\varphi_2 - \frac{2\pi}{c}i^3 \\ \delta\varphi_1 - \Delta\varphi_0 &= (\mu - 2\gamma)\varphi_0 + 2\tau\varphi_1 - \sigma\varphi_2 + \frac{2\pi}{c}i^4 \\ \delta\varphi_2 - \Delta\varphi_1 &= -\nu\varphi_0 + 2\mu\varphi_1 + (\tau - 2\beta)\varphi_2 + \frac{2\pi}{c}i^1 \end{aligned} \quad (6)$$

where $\varphi_0 = F_{ik}L^i\bar{M}^k$, $\varphi_1 = \frac{1}{2}F_{ik}(L^iN^k + \bar{M}^i\bar{M}^k)$, $\varphi_2 = F_{ik}\bar{M}^iN^k$ are the complex field strengths³. For a null field we can always choose the tetrad⁴ such that

$$\varphi_0 = \varphi_1 = 0, \varphi_2 \neq 0 \quad (7)$$

To make equations (2) and (5) consistent we must have

$$i^1 \neq 0, i^2 = i^3 = i^4 = 0 \quad (8)$$

Substituting (7) and (8) in (5) gives $\kappa = \sigma = 0$ for the L^i -congruence, which means that the radiation field propagates along shear-free null geodesics³.

From the conservation of charge equation $J^i{}_{;i} = 0$ it follows that on

$$\begin{aligned} Q, iL^i + QL^i{}_{;i} &= 0 \\ DQ &= -QL^i{}_{;i} \\ &= Q(\rho + \bar{\rho}) \end{aligned} \quad (9)$$

By a change of scale along L^i we can make $\varepsilon + \bar{\varepsilon}$ vanish and hence get the simple differential equation for ρ in Minkowski space

$$D\rho = \rho^2 \quad (10)$$

It is well known^{5,6} that an affine parameter r can be found on each curve of the L^i -congruence such that $D = \partial/\partial r$. This gives for equation (10) the general solution

$$\rho = (r + a + ib)^{-1} \quad (11)$$

where a and b are independent of r . The singular solution $\rho = 0$ giving zero expansion and zero twist is Bonnor's. From equation (9), Q must be constant in this situation. Taking $a = 0$ merely changes the origin of r on each curve but does not alter the problem. Thus equation (9) becomes on Γ

$$DQ = 2Qr(r^2 + b^2)^{-1} \quad (12)$$

which has the general solution

$$Q = K(r^2 + b^2) \quad (13)$$

where K is also independent of r . Clearly when $b = 0$ we see that Q must vanish at $r = 0$ and hence by affine transformations at every other point of the geodesic Γ .

Finally,

$$\begin{aligned} \rho &= 0 + i\omega \\ &= \frac{r}{r^2 + b^2} + i \frac{(-b)}{r^2 + b^2} \end{aligned} \quad (14)$$

showing that when $b \neq 0$ the L^i -congruence has non-zero local expansion θ and twist ω (refs. 2, 5 and 6).

Results of a Seismic Refraction Experiment on Rockall Bank

ROCKALL BANK (Fig. 1) is situated in the NE Atlantic 300 miles west of Scotland and represents the shallowest part of Rockall Plateau, a more extensive shoal area. The Plateau is less than 1,000 fathoms in depth and the Bank is less than 500 fathoms, culminating in Rockall Islet at its north-east end. Rockall Trough, 1,500 fathoms deep, separates Rockall Plateau from the continental shelf west of Scotland.

Fig. 1. The location of the seismic refraction experiment on Rockall Bank. The lines of shots and positions of receivers are shown.

A 150 nautical miles long reversed seismic refraction line, incorporating short split profiles at each end, was shot along Rockall Bank from RRS Discovery in the autumn of 1969 in order to obtain a thickness for the Earth's crust beneath the Bank. The internally recording sono-radio buoys of Cambridge University and the pop-up bottom siesmometers (PUBS) of the National Institute of Oceanography acted as receivers while Discovery steamed away firing charges up to 900 pounds at 150 nm.

About two hundred points from the sono-buoy data were used to construct a travel-time plot for the split and reversed profiles (Fig. 2). A plot of about forty points from the PUBS data, not included in Fig. 2, confirms the sono-buoy results. An offset of 0.4 s occurs in the 6.41 km/s line at 35 s from the north-east end of the profile. It can be attributed to a structural step in the refracting interface (Fig. 3b). Because of bad weather the refraction line was not completely reversed, so a velocity for the upper mantle was obtained in one direction only, being 8.2 km/s. The formulae of Ewing *et al.*¹ were used to calculate the velocities, depths and dips of the refracting layers of the crust. The data from the split profiles were used to calculate the shallow structure at each end of the line (Fig. 3a) and the data from the reversed part of the line were used to calculate the deep structure of the Bank (Fig. 3b).

There is no evidence for superficial unconsolidated sediment cover to Rockall Bank at either end of the line. Seismic reflexion profiling records over the Bank show that superficial sediments occur only as a thin layer and in pockets². The 3.8 km/s velocity measured at the north-east

Fig. 2. Travel-time plot for the seismic refraction experiment on Rockall Bank. Equations to the lines are expressed in the form: intercept time (s) + X /velocity (km/s).

end of the line is close to the 3.9 km/s obtained for basalts in the Faroe Islands and Iceland². Basalts have been dredged from Rockall Bank^{4,5} and Rockall Islet is probably a remnant of a Tertiary volcanic centre⁶⁻⁸. This evidence suggests that the 3.8 km/s layer may represent basaltic lava flows on Rockall Bank, perhaps as part of the Thulean volcanic province⁴. The 5.85 km/s velocity found only at the south-west end of the Bank is within the range of velocities assigned to the granitic layer of the crust^{9,10}, but here it may well represent very old sedimentary rocks. The shallow structure is, no doubt, highly variable over the

length of the refraction line, so to calculate the deep structure a mean velocity of 4.8 km/s was used for the top crustal layer. The 6.36 km/s velocity obtained for the upper crust is well determined, but the 7.02 km/s velocity for the lower crust is less well determined. Both these velocities are at the upper limit of those quoted for a typical continental crust^{9,10}. The interface at 15 km depth appears to be a moderately strong refractor on the evidence from the travel-time plot, and can be identified with the Conrad discontinuity. The most important result of the whole experiment, however, is the value of approximately 31 km for the depth to the Moho beneath Rockall Bank.

This direct evidence for the continental thickness of the Earth's crust beneath Rockall Bank, together with the evidence from compiled gravity and magnetic data, justifies the retention of Rockall Bank in the pre-drift reconstruction by Bullard *et al.*¹¹ of the North Atlantic continents.

I thank Dr D. H. Matthews for his help and advice at sea and on land, and Dr A. S. Laughton, Dr R. B. Whitmarsh and the master and officers of RRS Discovery for their help at sea.

Origin of the Hurd Deep, English Channel

THE Hurd Deep, the largest deep in the English Channel, is a linear depression about 95 miles (150 km) long, 1-3 miles (1.5-5 km) wide and about 30-50 fathoms (55-90 m) deeper than the adjacent sea floor. The depression follows a relatively straight course WSW from near the north-west corner of Cherbourg Peninsula and runs parallel to the general structural trend of the western English Channel.

sions which form a tributary system. These depressions are partially filled channels, and they can be traced eastwards towards the Seine, Somme and Straits of Dover¹².

The Hurd Deep is the remnant of a much larger channel system, now partially filled in. We conclude that the erosion of the channel now forming the Hurd Deep was caused by both fluvial and tidal action. Fluvial erosion was related to downcutting by rivers extended across the continental platform during periods of low Pleistocene sea-level. During this time, the lower reaches of the river system would have been subjected to strong scouring by

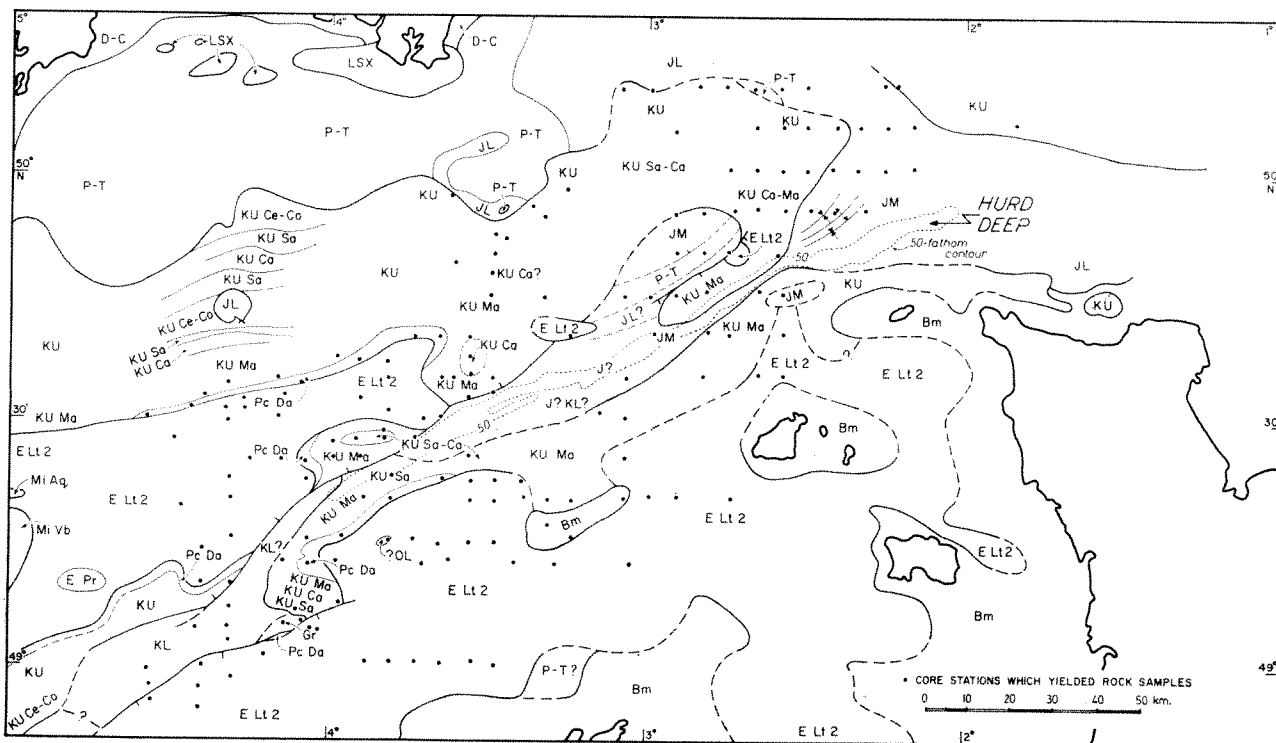

Fig. 1. Geological map of the Hurd Deep area, English Channel. Bm, Basement; LSX, Lizard-Start complex; Gr, Granite; D-C, Devonian Carboniferous; P-T, Permian-Triassic; JL, Lower Jurassic; JM, Middle Jurassic; KL, Lower Cretaceous; KU Ce, Upper Cretaceous, Cenomanian; KU Co, Coniacian; KU Sa, Santonian; KU Ca, Campanian; KU Ma, Maestrichtian; Pc Da, Palaeocene Danian; E Pr, Eocene, Priabonian; E Lt2, Eocene, Upper Lutetian; Ol, Oligocene; Mi Aq, Miocene Aquitanian; Mi Vb, Miocene Vindobonian.

Detailed geological mapping of the area by the Bristol University Group has brought to light new data which permit a critical assessment of the numerous hypotheses that have been put forward to account for the origin of the deep. These hypotheses suggest river erosion¹⁻³, faulting and structural control⁴⁻⁶, glacial erosion^{7,8}, a karstic origin in chalk⁹ and tidal erosion^{3,10}.

Using a combination of gravity coring and sparker surveys, the Bristol University Group has produced a detailed map of the solid geology of the Western Approaches to the English Channel¹¹. The part of this geological map in the region of the Hurd Deep shown as Fig. 1 is based on 52 sparker traverses and some 200 gravity core stations.

The map clearly indicates an erosional origin. For about 60 miles (95 km) erosion has cut through chalk sediments into the underlying Jurassic rocks. The fact that for over 80 miles (125 km) the Deep is floored by Jurassic clays, silts and thin limestones renders the hypothesis of karstic origin⁹ untenable.

Further support for an erosional origin comes from the sparker profiles which reveal that the Hurd Deep is a partially filled channel. The depth of fill in the channel is variable, reaching 200-300 feet (60-90 m) in some places and decreasing to zero at the south-western end of the feature. At the north-eastern end there are three depres-

sions which form a tributary system. As sea-level rose, this latter mechanism has, no doubt, been a major factor in maintaining the deep up to the present day, because the maximum depths in the feature now occur in the region of the strongest tidal currents¹⁰.

Himalayan Ridge in the Light of the Theory of Continental Drift

A UNIQUE feature of the geology of the Himalayas is the presence to the north of the Great Himalayan Range of a complete sequence of marine fossiliferous rocks ranging in age from the Cambrian to Eocene and an enigmatic absence of fossils in the pre-Tertiary sediments lying to the south of the range¹. A notable exception is found in Kashmir where fossiliferous Cambrian to Jurassic marine rocks lie to the south of the Great Himalayan Range as a result of the Kashmir Nappe². Geologists working in the Himalayas have tried to explain this anomaly by erecting a hypothetical barrier between the northern and southern basins to prevent the migration of animals and plants from north to south. This barrier was called by Wadia³ a "geanticline within the main geosyncline". Pande and Saxena⁴ thought that the geanticline or central barrier was formed during the Ordovician times. Fuchs⁵ named this imaginary barrier "Himalayan Ridge" and thought that it was formed after the Caledonian orogeny. It has also been suggested that this geanticline or ridge has been subjected to denudational processes since its origin in the early Palaeozoic times, but it has become the highest mountain range in the world and it is still rising.

Recent palaeomagnetic studies on the Deccan Plateau basalts have revealed that the Indian Peninsula has drifted about 5,000 km in a northerly direction since the end of the Cretaceous at a rate of about 7 cm a year⁶. The Indian Peninsula probably lays further to the south in the pre-Cretaceous times. This important discovery has given strong support to Wegener's theory of continental drift⁷. Geologists working in the Himalayas, however, seem to have overlooked the great implications which follow from the above discovery. We should like to point out that if the Indian Peninsula along with the sediments laid down on its northern margin and which now constitute the Lesser Himalayan zone lay at least 5,000 km to the south of its present position in late Cretaceous, then the presence of a geanticline or ridge becomes superfluous. The above contention is supported by the fact that the Himalayas have a maximum width of 400 km. Gansser⁸ suggested a maximum shortening of the crust of the order of 500 km during the Himalayan orogeny. This would mean a maximum width of only 900 km for the so-called northern and southern geosynclines. What, then, happened to the remaining 4,000 km of land or sea or both?

In the light of the above facts we suggest that the Tethyan zone lying to the north of the Great Himalayan and the Lesser Himalayan zone lying to the south of the range were at least 5,000 km apart. This would explain faunal differences of the two and obviate the necessity of having a ridge in pre-Tertiary times.

Evidence for Salt Deposits in the Appalachian/Caledonian Orogen

ALBITE-oligoclase feldspar concentrations occur abundantly in the Eocambrian to Lower Ordovician metasediments, along the entire metamorphic Caledonian-Appalachian mountain chain. In Spitsbergen (refs. 1 and 2 and personal communication from W. Horsfield); Stavanger, Norway; SE Scotland; Antrim, N. Ireland; Co. Mayo, Ireland³; Burlington Peninsula, Newfoundland; Pennsylvania; Dutchess County, New York⁴; and Maryland, particular attention has been given to the albite schist association.

The origin of the large amounts of Na₂O involved in these albite schists is of great importance. It is usually suggested that regional soda metasomatism, usually involving fluids from granites, soda granites and their associated migmatites, is responsible and sedimentary or even volcanic origins have also been suggested. A completely satisfactory explanation for these enormous quantities of Na₂O has, however, not yet been given.

The albite schists occur in different parts of the sedimentary pile, and they are associated with similar lithologies. Volcanic rocks are common, but are not obvious in all cases. In most areas, the albite schists are stratigraphically and lithologically controlled and a primary origin of the sediments and element distribution can be demonstrated. The regional metasomatic origin, which is preferred in many cases only because a primary origin for the amounts of Na₂O and K₂O could not be found, therefore seems unreasonable.

Thick salt layers are often associated with subsiding rifts, in which the salt and clastics directly overlie a volcanic basement. In the Red Sea, Miocene basal clastic sediments are overlain by gypsum, probably of continental origin. Upper Miocene sediments are brackish to marine, and by the Pliocene, marine sedimentation was widespread. Large thick evaporite and associated metal concentrations are known to exist in the sediment piles up to 15 km thick. Of very great interest are the hot brine pools found in the axial rift of the Red Sea⁶. Their composition strongly supports the evidence that they are not a single concentrate developed by extreme evaporation, and suggests that they are a resolution of previously deposited halite and gypsum deposits together with their trace elements, long since parted from their bittern, which remained in solution and were possibly deposited elsewhere. It is clear that the chemistry of the present hot brines involves numerous complex chemical reactions and inter-relationships. Element enrichment is comparable with that of salt in salt domes of non-volcanic areas.

Further south, along the rift valleys of East Africa, extensive continental deposits of limited thickness contain large amounts of saline evaporites, zeolites, authigenic sodium feldspars and potassium (ref. 7 and personal communication from J. A. Van Couvering). These are partly a direct consequence of the associated volcanics along the fault scarps.

Around the margins of the present Atlantic Ocean, salt is widespread. Association of extensive salt doming with oil and gas is common⁷ and evaporite basins are common along the African coast (Fig. 1). It has been suggested⁸ that salt deposition is genetically related to the initial stage of rifting and was widespread during the initial opening of the present Atlantic Ocean, in certain latitudes. Elsewhere, such as in the western Mediterranean, segments of ocean floor formed during the Tertiary are now extensively covered by clastic sediments which include known salt deposits⁸.

In a general model describing the opening of a new ocean basin⁹ in terms of plate accretion, an integrated relationship between graben formation, rapid sedimentation and seafloor spreading are envisaged. The situation can be related rather well to the present situations in the

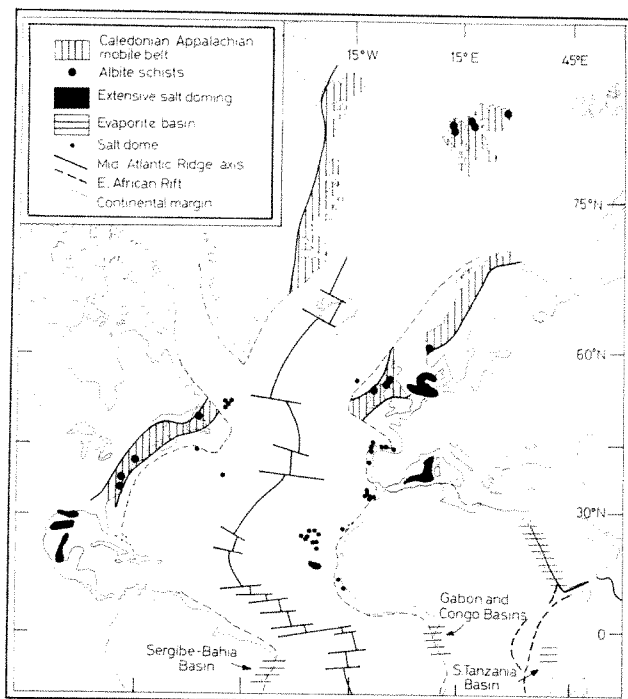

Fig. 1. Albite-schist occurrences in the Appalachian/Caledonian Orogen and salt occurrences in the Atlantic Ocean.

African rift valley and the Red Sea, and at a later stage to the present Atlantic ocean.

It has been suggested that a proto-Atlantic ocean¹⁰ opened and closed along the Caledonian-Appalachian suture¹¹ in a complex manner in terms of plate tectonics¹². Marginal sedimentation along the proto-Atlantic continental margins was recognizably very similar along the entire site. Rapid deposition of coarse shallow water clastics are followed by extensive quartzites, carbonates, volcanics and graywackes.

Evaporites are suggested to have been a major early component of these thick sediment wedges along the proto-Atlantic continental margin. This is indicated by extensive halite pseudomorphs in Greenland¹³, but it must be realized that the evolution of salt deposits, subsequent to deposition, can be extremely complex¹⁴. Minerals may be remobilized and widely disseminated, or concentrated in layers throughout the sediment pile. The premetamorphic evaporites almost certainly underwent complex authigenic growth, brine distribution and redistribution, normal geothermal metamorphism, and complex salt tectonics, under the sedimentary overburden during prolonged diagenesis, and this could explain the mainly stratigraphic variations. The numerous possibilities of remobilization of the salt components during orogeny may be even more complex and this may be why extensive evaporites have so far not been described in metamorphic terrains. That they exist, however, has been shown by the presence of gypsum, halite, graphites and paraffins in areas such as the Grenville belt¹⁵.

The evaporites and related sediments (personal communication from J. F. Dewey) may remain on a descending oceanic plate, the Arabian Shield evaporites. Or, in conditions of orthotectonic deformation and metamorphism, the salt components may undergo complex reactions with co-existing silicates in the elevated P and T conditions. This leads to the extensive development of albite oligoclase schists in large areas of the Caledonian-Appalachian belt, and to the sometimes widespread developments of scapolite^{16,17}.

The distribution after metamorphism is still essentially stratigraphically and lithologically controlled, which

agrees well with the postulated sedimentary origins of the soda.

This may thus reflect a much greater relationship in some areas between mineral assemblages and the original chemical composition than has previously been thought. Certainly, the large scale regional metasomatic processes so often envisaged in this context need not necessarily have occurred.

I thank Dr J. F. Dewey for his help and encouragement and Dr M. Max, Mr M. Crow and Mr W. S. F. Kidd for critical discussion. The work was supported by a Shell postgraduate scholarship.

Voids in Nickel irradiated with Electrons after Previous Argon Ion Bombardment

VOIDS can be produced in some metals by high fluence neutron irradiation at temperatures between $0.3 T_m$ and $0.5 T_m$, where T_m is the melting temperature. The effect was found first in stainless steel¹ and subsequently in several pure metals including nickel^{2,3}. Void formation

Fig. 1. Large faulted loops in nickel, electron irradiated at 430° C without previous ion bombardment; foil normal (110), $g = (002)$.

Fig. 2. Voids and dislocations in nickel given the identical electron irradiation to that of Fig. 1 but after argon ion bombardment.

causes dimensional instability and is liable to be a serious technological problem in fast reactor fuel cladding. This note reports some preliminary results on the production of voids in nickel by electron irradiation in the beam of a high voltage electron microscope (HVEM) following an initial argon ion bombardment. The HVEM offers a convenient method of studying electron displacement damage effects⁴ and in this work we used a Hitachi 1 MV instrument with a heating stage.

Vacuum annealed nickel sheet of 99.995 per cent purity was electro-polished to form thin foil specimens, some of which were then bombarded with 130 kV argon ions to various fluences before insertion in the HVEM. Electron bombardment was at 1 MV with a beam current of 0.4 μA (measured below the specimen) and with a beam diameter $\sim 3 \mu\text{m}$. A 1 MV electron can transfer to a nickel atom a maximum of 70 eV, sufficient to displace two atoms at most. If we take the displacement cross-section as 34 b, the fraction of atoms displaced per second is 1.6×10^{-3} . All nickel specimens placed in the HVEM beam are observed at first to develop black spots which then grow and interact. In a specimen not previously ion bombarded, electron irradiation at 430° C results in the growth of very large faulted loops (see Fig. 1), similar to those previously observed in copper irradiated with electrons at an unknown temperature⁵. An ion bombarded specimen contains initial black spot damage but no features identifiable as voids. As exposure to the HVEM beam continues, a totally different electron irradiation damage structure is produced. Fig. 2 shows a nickel specimen bombarded with 130 kV argon ions to a fluence of $2 \times 10^{18} \text{ m}^{-2}$ and then irradiated in the HVEM beam for 40 min at 430° C. A network of dislocation tangles and loops has been produced, together with a high density of small, approximately square features, some darker and some lighter than background. These have the characteristics of diffraction contrast from small voids⁶; the contrast may be positive or negative depending on the excitation error and on the vertical position of the void. The features are therefore identified as voids within the foil. The void density is $2 \times 10^{15} \text{ m}^{-2}$ for a foil thickness of 130 nm. The images have edges along the projected (100) directions and the average edge length is 6 nm. In some cases voids lie along a line, possibly that of a dislocation which has subsequently moved.

Calculations were performed to determine whether the features could be equilibrium bubbles resulting from the argon ion bombardment. Taking the surface energy to be 1.6 J m^{-2} , the observed features would require 8×10^{18} gas atoms m^{-2} , a factor of 4 greater than the actual argon ion fluence. Further, a specimen ion bombarded to a fluence 100 times greater gave features of similar size and density. Consequently the conclusion is that the features cannot be equilibrium bubbles and must be regarded as voids.

This is the first observation of void formation by electron irradiation. The voids were only found in pre-bombarded specimens indicates the importance of either or both gas atoms and point defect clusters on the nucleation process. The result shows that void growth occurs during irradiation which produces only mono-vacancies or di-vacancies but no larger cascades. Irradiation in the beam of a HVEM offers an excellent method of studying the formation and properties of voids. The effects of varying the pre-bombardment conditions and the HVEM beam irradiation conditions are being investigated in detail and will be reported elsewhere.

Overexcitation Interferences in Atomic Absorption Spectrophotometry with an Air-Acetylene Flame

In recent years, atomic absorption spectrophotometry has established itself as a valuable analytical technique for trace metal analysis and a large number of procedures are now available for the determination of metals in a wide variety of matrices^{1,2}. In most cases, only qualitative interference effects have been considered, and very little research appears to have been directed towards the flame chemistry of the technique. This would help to elucidate the mechanism of metal vapour production and the causes or mechanisms by which flame interferences are produced. The only interference phenomena which are now well established are those relating to ionization and to the formation of thermally stable compounds such as single or mixed oxides.

We have recently been examining interference effects of transition metals and have noted the anomalous effect of flame mixture ratio (air : acetylene) on the absorption of several metals. Solutions of metal salts, as sulphates or nitrates, which would be expected to yield a metal oxide (MO) as the penultimate species before the formation of free metal atoms, exhibit a sharp drop in absorbance occurring at a particular mixture ratio and all mixtures containing more acetylene on the fuel-rich side of the flame. In Fig. 1 the absorption due to iron at various flame mixture compositions is illustrated and shows a sharp drop at acetylene : air ratios greater than 0.85. These effects are not observed in chloride medium and only occur under conditions which would be expected to favour oxide dissociation (that is fuel rich) and in fact the variation in emission intensity of the FeO band (measured at 574 nm) decreases with increasing acetylene concentration, which supports this hypothesis.

Our results to date indicate that this phenomenon is most prevalent for those elements exhibiting complex atomic spectra in which there are possibly long lived metastable states of higher energy than the ground state. It seems likely that the loss of absorption in a fuel-rich air-acetylene flame may be caused by the production of metal atoms in some of these states rather than in the ground state and that some of the interferences which have been reported^{3,4} to occur in these conditions (that is rich flame, sulphate medium) may also be attributed to the same phenomena.

Fig. 1. Variation of the absorption and emission of several species with respect to flame composition. Curve A, 25 p.p.m. iron (III) sulphate in 10^{-3} M sulphuric acid (absorption). Curve B, emission due to FeO, produced from a solution of 1,000 p.p.m. iron as iron (III) sulphate. Curve C, emission due to C_2 . Curve D, 25 p.p.m. chromium (III) sulphate in 10^{-3} M sulphuric acid (absorption). Curve E, 25 p.p.m. cobalt (II) sulphate in 10^{-3} M sulphuric acid (absorption). The position of stoichiometric composition is indicated at F.

The absorption profiles (with respect to fuel-air ratio) of Fe, Cr, Ni, Co, Cu, Ru, Mn, Ca, Mg, Zn in both sulphate and chloride media were recorded using a standard Perkin Elmer 290 Atomic Absorption Spectrophotometer with an air flow rate held constant at 46.1 min^{-1} (corrected to atmospheric pressure) and acetylene flow rate varied between 2.0 and 4.8 l min^{-1} . Standard Perkin-Elmer hollow cathode lamps were used in each case and operated at the recommended current and wavelength settings. Percentage absorption measurements were observed with the centre of the light beam at 10 mm above the top of the standard 50 mm slot burner. Emission data were obtained using the manufacturer's emission accessory with the flame placed at 90° to the light path and masked to give a 2 mm deep horizontal slit centred at 10 mm above the burner head.

The sharp drop in absorption due to iron, chromium and cobalt at all acetylene to air ratios greater than the particular critical ratio, which varies from element to element, is shown in Fig. 1, and we have found similar behaviour with Ni and to a lesser extent with Cu. The effect is, however, absent for Mn and Zn. The effect may also be observed at similar mixture ratios in air-propane flame but is absent from the air-hydrogen flame in which carbon species are not present. Severe interferences have been reported^{3,4} for iron in these fuel-rich conditions and similar interferences are observed with Co, Ni and Cr.

The mixture ratios at which these effects are observed coincide with the region in which emission from carbon species such as C_2 , CH and CO are found to persist at higher parts of the flame where absorbance measurements are normally made (as distinct from the primary cone where such emission may be observed in all flame conditions).

The variation of C_2 emission intensity with flame gas mixture measured at 517 nm is shown in Fig. 1, and the CH profile measured at 430 nm is very similar. Over-excited C_2 or CH species, among others, are known to occur in these conditions⁵, and arise from reactions such as

where X is an energy acceptor (for example, another C_2 or CH molecule) which can accept the 176 kcal of energy liberated in this reaction. Such overexcitation is most strongly observed in an air-acetylene flame and does not occur to any significant extent in hydrogen flames where the flame reactions are less exothermic⁵. Over-excitation of metal atoms has been confirmed for several metals⁶⁻⁷ and may occur through reaction (1), where X is the metal atom, by direct overexcitation energy transfer or most likely, through the reaction of the metal oxide species with an overexcited molecule, for example C_2^* ,

It would be most prevalent in conditions in which the concentration of oxygen is low and fails to react with all the C_2 produced, in a fuel-rich air-acetylene flame.

Additional evidence for this hypothesis is to be presented elsewhere, but these effects illustrate the importance of careful control of operating conditions with respect to both flame parameters and the chemical composition of the samples and standard solutions used in atomic absorption spectrophotometry, even for elements previously considered to be relatively interference free.

Homogeneous Photocatalysis by Organic Dyes in the Liquid Phase

EXPERIMENTS using organic semiconductors as catalysts are interesting for several reasons. Organic semiconductors have a molecular lattice and the parameters of the catalyst can therefore be altered by altering the molecules forming the lattice. Organic chemistry techniques also enable single molecules to be synthesized in a tailor made fashion.

We have studied various heterogeneous reactions catalysed in dark and light by organic semiconductor crystal powders in experiments in a static apparatus. These reactions are oxidation of carbon monoxide photocatalysed by crystal violet, metal free and Cu-phthalocyanine, the oxidation of H_2 to H_2O and the decomposition of N_2O photocatalysed both by metal free and Cu-phthalocyanine. Together with the catalytic reaction, a

more or less pronounced decomposition or oxidation of the organic catalyst occurred, and we have tried to suppress this by varying the reaction conditions and the experimental techniques. The decomposition of formic acid and of isopropyl alcohol with *p*-bromanil and *p*-chloranil as catalysts has been established by gas chromatography, without any disturbance. These reactions are now being studied in more detail.

In reactions catalysed by crystalline dyes, are the crystal properties or the structure of the single surface molecule of the dye responsible for the catalytic processes observed? Furthermore, because the dye molecule is rather large in comparison with the substrate molecule, the interaction of the substrate molecule with the crystal surface may involve only one surface molecule of the dye. This interaction would certainly be influenced by the interaction of the surface dye molecule with the lattice of the dye. It is therefore necessary to carry out experiments which can distinguish between the catalytic activity of the dye molecule because of its position in the surface of the semiconducting lattice and the catalytic activity of the dye molecule because of its own chemical structure. Experiments in which single dye molecules act as catalysts or sensitizers, for example, on studies of homogeneous catalytic reactions in the liquid phase, would do this.

Oxidation of isopropyl alcohol is a convenient reaction, because the alcohol is the solvent for the dyes and reactions of other solvent molecules can therefore be avoided. Earlier investigations¹⁻⁴ have led us to choose triphenylmethane dyes as catalysts.

The reaction is carried out in small 'Pyrex' flasks containing 12 ml. of the solution of the dyes in isopropanol and 20 ml. oxygen at atmospheric pressure. The concentration of the dyes is 10⁻⁶ moles/ml. The flasks are mounted in a water thermostat and are illuminated by 40 W light bulbs. At intervals of several hours 1 µl. of the reacting solution is removed by a Hamilton microlitre syringe and is analysed in a 116 E Perkin-Elmer gas chromatograph (carrier gas He, 99.995 per cent from Linde; carbowax column) with a Sargent recorder (2.5 mV).

It was found that no reaction of the isopropanol occurs either in the dark or in the light unless a dye is added, but no dark reaction can be seen with any dye. No reaction decomposition or oxidation products of the dyes can be seen in the chromatogram; however, a slight decomposition of some of the dyes is seen from ultraviolet spectra of the solution. The reaction occurs according to the equation

CO₂ is also formed to a very limited extent (about 1/100 of the amount of acetone), but it is not clear whether this is from a parallel or from a subsequent reaction. Acetone

undergoes no reaction when used as solvent for the dyes.

The photocatalytic activity of the dyes at 50 and 70° C is shown in Table 1 in terms of maximum amounts of acetone formed after 48 h. A maximum of 50 units corresponds to 2 per cent conversion of isopropyl alcohol. In addition, the semiconductor properties of the solid dyes^{5,6} and the fluorescence of the molecules⁷ are given in the table. The first four dyes belong to the fluorane type (triphenylmethanes with an oxygen bridge). With the exception of erythrosine, they exhibit a high activity at 70° C and less activity at 50° C. With one exception, the catalytic active dye molecules form *p*-conducting crystals; all molecules are fluorescent.

The second group (5, 6) are molecules of the phenazine type, a nitrogen atom forming the bridge between the phenyl rings. They are clearly fluorescent vacuum semiconductors, with no catalytic activity. The molecules of the third group (7-11) are the triphenylmethane dyes without bridge atom. Again, they have no catalytic activity, are *n*-semiconductors and do not fluoresce. The phthaleins of the fourth group (12-14) have features similar to those of the triphenylmethanes.

The last three dyes are not triphenylmethane dyes and these results will not be discussed here.

At the present state of investigation, we may conclude that the catalytic activity of the dye molecule is connected with the mobility of the charge carriers in the ground state and with the immobility of the charge carriers in the excited state⁴, these being the properties causing *p*-conductivity in a molecular lattice. The interaction between substrate molecule and sensitizer molecule may be related to the charge transfer from molecule to molecule in the semiconductor lattice. As the activity of the fluorescent molecules shows, catalytic activity is also connected with the existence of a long living triplet state of the molecule¹⁻³.

As shown by the example of the phenazine dyes, however, the existence of a fluorescing triplet state is not a sufficient criterion for catalytic activity. We cannot yet say whether the *p*-conductivity or the oxygen bridge is the essential parameter, but both may be concerned. Furthermore, chemical aspects have to be considered: the iodine substituents of erythrosine are rather large and the low activity of erythrosine may be caused by sterical hindrance.

More complete conclusions cannot yet be drawn and we are now studying the various problems in more detail.

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for sponsoring this investigation.

Kerr Effect in Polymers

RECENT observations on bulk samples of polystyrene and polymethyl methacrylate have shown the existence of a Kerr-type electro-optic effect in these materials, the application of an electric field to the sample giving rise to a change in optical refractive index which is proportional to the square of the applied field, for light polarized normally to the applied field.

The observations have been made by constructing a Fabry-Perot interferometer cell with the polymer sample as the optical medium^{1,2}. The interferometer mirrors serve in addition to their normal function as electrodes for the application of a d.c. field of approximately 10^6 V/m, with a superimposed low-frequency a.c. field of similar magnitude. The effect of the two fields is to change the optical path length between the mirrors, and hence to amplitude-modulate a helium-neon laser beam passing through the electro-optic cell. Detection of the signal is by a photo multiplier tube and suitable electronic amplifying and display equipment.

The estimated magnitude of the Kerr coefficient for PMMA at 1 kHz is about 10^{-12} mV⁻² (10^{-5} cm/statV²), which is about half the value quoted in the literature for nitrobenzene. The corresponding figure for polystyrene appears to be considerably larger, but has not yet been measured. A curious feature of the effect is that in both materials it is associated with a relaxation time of about 10^{-4} s; in the case of PMMA there is a strong resonance at 15 kHz, followed by a rapid fall to near zero, while for polystyrene the modulation depth decreases steadily as the frequency is increased beyond about 5 kHz, without showing a resonance peak.

The possibility that this behaviour could be due to diaphragm resonances of the samples has been eliminated by repeating the experiments on disks of different thicknesses and diameters.

So far the experiments have only been carried out on uncharacterized materials at room temperature. The relaxation frequency we have observed does not seem to correspond to any other known room temperature relaxations in the dielectric properties of these materials, but a recent survey by Block and North³ reports similar relaxation frequencies for dielectric properties of a rod-like polymer (in this case poly- γ -benzyl-L-glutamate) in solution, the frequency being proportional to the reciprocal of the square of the molecular weight of the polymer. We hope to report later on the influence of molecular weight on our observations, when suitable characterized samples are available.

Some theoretical studies and a considerable amount of experimental work on the Kerr effect in various polymers in solution have been reported⁴⁻¹⁵, but our observations seem to be the first to be reported on solid polymer samples.

Structure of Anomalous Water and Its Mechanism

SINCE the discovery of "anomalous water"¹, several models²⁻¹² have been proposed for its structure. I derive here a model based on present experimental knowledge, and then explain its mechanism.

With sp^3 orbitals for oxygen, the structure of water includes two "long pairs", which may be the media for hydrogen bondings. In Fig. 1a, we assume that such water molecules may be polarized by two small (structure making) cations, stretching one of the O—H bonds. The stretched hydrogen may become more positively charged and act as a cation to polarize the neighbouring water molecule and produce a chain effect. This description fits the discovery of a chain of water molecules in the field ionization of water¹³. The above mechanism may be regarded as analogous to the idea of "localized hydrolysis" of Robinson and Harned¹⁴ in aqueous electrolyte solutions. If the charge of the cation were strong, the stretched hydrogen might be ionized and leave the hydroxyl group attached to the cation with species like $[(HO)_nCu(OH)_2Cu(OH_2)_n]^{2+}$ (ref. 15), and $[(H_2O)_4Al(H-OHO-H)_2Al(OH_2)_4]^{4+}$ (ref. 16). This approach is consistent with the fact that the Raman spectra of water in concentrated ionic solutions of a wide range of salts¹⁷ as well as anomalous water³ show nearly identical peak frequency shifts from the $3,400\text{ cm}^{-1}$ band of normal water.

In our model for anomalous water, the silicon ions at the surface inside the quartz capillary induce with charge

Fig. 1. a, The structure of a water molecule, with sp^3 orbitals for oxygen, being polarized by two positive charges and stretching one of its O—H bonds. \circ , Oxygen; \bullet , hydrogen; \oplus , small cation; —, unstretched O—H bond; ---, stretched O—H bond; \cdots , lone pair of oxygen. b, The arrangement of a six-membered ring formed by charge induced effect.

the arriving water molecules into forming a water molecular chain. For the small size of the capillary (2 to 4 μm in diameter), however, the chance of forming a ring is greater. According to Hertl and Hair's study of water adsorption on silica⁷, a six-membered ring is indicated. Molecular orbital calculations from first principles have also predicted that cyclic structures are the most stable¹⁸. Allen and Kollman⁹ have derived the six-membered ring arrangement theoretically. In the present model, the arrangement of the ring is shown in Fig. 1b, which can be seen as an equilibrium arrangement maintained by six hydrogens and six hydroxyl groups. By maintaining the sp^3 orbitals for oxygen, the ring is formed in the shape of a "chair" as shown in Fig. 2a. The ring may move on the surface.

In Fig. 2a, the dash-lines enclosing the ring are in the shape of a half-height pyramid with the (111) plane as its base. The sides of this base and its height are $(4\sqrt{6}/3)R$ and $(4/3)R$ respectively. R is the O-to-O distance of the

Fig. 2. *a*, The arrangement of a six-membered ring according to the sp^3 orbitals of oxygens. Only the oxygens are shown. The oxygens are labelled and the ring is indicated by the thick solid lines. The unstretched O—H bond is represented by the thick dashes. The surrounding thin dash-lines in the shape of a half-height pyramid with the (111) plane as its base are a ring unit. *b*, The top view of three ring units hydrogen bonded together to form a layer.

Fig. 3. The stacking of the six-membered rings into layers. Only the oxygens are shown. The sequences of layers for the labelled oxygens are indicated. *a*, Top view; *b*, side view. Its unit cell is a hexagon.

Fig. 4. One way of stacking the rings into (C9) type structure. *a*, The unit cell; *b*, the scheme of layer stacking.

ring. Fig. 2b shows the top view of this half-height pyramid and demonstrates how the rings can join together into a layer. If the ring in Fig. 2a rotates $2\pi/6$ about its *c*-axis and sits on top of another ring at its original position, the layers can be stacked together as shown in Fig. 3. It is assumed that, when the ring is isolated, the hydroxyl groups are just like any non-hydrogen bonded hydroxyl group. When bonded into layers, the hydrogen of these hydroxyl groups is shared by two oxygens and each oxygen is surrounded by four hydrogens. Equilibrium may be reached by forming the in-between ring hydrogen bonds with the same symmetry as those within the rings. Such a stacking, as in Fig. 3, has a hexagonal unit cell of $a = (2\sqrt{6}/3)R$ and $c = (8/3)R$ for twelve molecules. All the other ways of combining the rings give a structure of the *anti* β -Cristobalite SiO_2 (C9) type (diamond (A4) type structure if we consider only the oxygens), with $a = (4\sqrt{3}/3)R$ for eight molecules. Figs. 4 and 5 show two of them. Whichever way the rings are stacked, the average volume for a ring of six molecules is always the same, being $(16\sqrt{3}/3)R^3$. Although it has been suggested⁴ that the value of *R*, the O-to-O distance, is 2.3 Å, similar to that of F...H...F, this value has since been found to be wrong. Nakamoto and co-workers¹⁹ have established a relationship between the stretching frequencies of H and the X...H...X distances in hydrogen bonds which shows that there are two separate curves for the O—H...O and F—H...F hydrogen bonds. From the reported stretching frequency of 1,595 cm^{-1} for anomalous water⁴, one may estimate its O-to-O distance as 2.4 Å from the plots of Nakamoto and co-workers¹⁹. They have also found that, in strong hydrogen bonds, the O—H distance increases exponentially as the O—H...O distance decreases, suggesting that for hydrogen bonds of ~ 2.45 Å the hydrogen will be centred. By taking the O-to-O distance (*R*) as 2.4 Å, the present model gives the density of the anomalous water as 1.4 g cm^{-3} , which is equivalent to the largest experimental figure²⁰. From the same known stretching frequency⁴ of 1,595 cm^{-1} , one may also estimate the "hydrogen bond" energy (per bond unit) as -31 kcalories mol^{-1} (-130 kJ mol^{-1}) from the relationship established by Lamberts and co-workers²¹⁻²³.

The anomalous water is therefore formed as six-membered rings in a "chair" shape, hydrogen bonded to each other into a close-packed diamond-like arrangement. The O-to-O distance is taken as 2.4 Å and the hydrogen is centred between the two oxygens. Each oxygen is in turn surrounded by four hydrogens. The hydrogen bonds in anomalous water are believed to be charge induced and strong. The whole network may be regarded as an equilibrium arrangement maintained by H^+ and O^{2-} with some OH^- at the boundary of the column—these OH^- groups may form hydrogen bonds with the oxygens available at the silica surface, which then eliminate the non-hydrogen bonded OH^- groups. Such a structure for anomalous water probably represents the most ordered structure of water. Its ordering mechanism may be in evidence near the water-solid interfaces discussed by Drost-Hansen²⁴ and the super-cooled water found by Frank^{25,26}. One may certainly find the same mechanism in clay, soil, tissue and cells. It may also solve the question of why water can reach the top of a very tall tree.

Pyrite Crystals in the Parenchyma Cells in Wood of Fossil Root

VERY small octahedral crystals (1 micron–20 micron) of iron pyrite have been found in the ray and wood parenchyma cells in parts of a fossil root of Oligocene age. The black humified wood is elsewhere partially replaced by veins of pyrite, as commonly seen in fossil wood of this

Fig. 1. Radial section of wood showing horizontal tiers of ray cells containing crystals. A vertical row of wood parenchyma cells is arrowed at top right ($\times 60$).

sort. The wood, illustrated in Figs. 1 and 2, was taken from one of many roots observed in the Hordle Cliff section of the Lower Headon beds near Milford-on-Sea, Hampshire. Similar roots occur in exposures of these beds at Totland Bay, Isle of Wight, and in both places the roots are in the position of growth¹. All the wood that we have examined anatomically is of a single type and, although some of the finer diagnostic features are not well preserved, it is closely similar in structure to the wood of *Taxodium distichum* (swamp cypress). We cannot, however, ignore the possibility that the roots belonged to the Tertiary *Sequoia couttsiae* which is prominent among the plants identified from other remains in the Lower Headon beds². A full description and discussion of the identity of our material will be presented elsewhere.

Microscopic pyrite, in the form of crystals and framboidal spherules, is common in dark shales and muds, and where it occurs in recent sediments it is a clear indication of early syngenetic formation of iron sulphide. A feature of especial interest is the constant association of the pyrite in these sediments with organic material, and pyrite is often found within the walls of diatoms, foraminifera, and plant spores and pollen grains^{3,4}. Coleman has recently described⁵ the replacement by pyrite of hollow rotted rootlets in freshwater clays of the Mississippi delta.

The precise role of organic matter in the early formation of pyrite is difficult to assess. There can be little doubt that the cells of animals and plants do not normally contain sufficient sulphur to account for the quantities of sulphides produced in sediments; and decomposing organic matter would not be capable of reducing sulphate to any appreciable extent in the absence of sulphur bacteria⁶. It has been suggested that pyrite spherules are the remains of sulphur bacteria or some other organism which deposited sulphides in their cells⁷, but pseudomorphic bacterial cells have not been seen in the pyrite of spherules, nor was any organism found to be directly precipitating pyrite in Recent sediments which contained organic material in which pyrite had formed⁸.

Fig. 2. Crystals at higher magnification ($\times 600$).

Preferential mineralization of organic material is clearly significant in fossilization⁹, and has some relevance to the genesis of certain ore deposits⁹. Emery has stressed¹⁰ the importance of the creation of a microenvironment within shells of decomposing diatoms, foraminifera and the like, which become infilled with pyrite. The localization of masses of tiny pyrite crystals in the parenchyma cells of our fossil root certainly supports the view that the microenvironment within the dead or dying tissue is an important factor in the early formation of pyrite. The parenchyma cells are the only cells which contained protoplasm, and these cells have provided the essential conditions that promoted the crystallization or precipitation of iron sulphide from the solution infiltrating the rotting root. The actual presence of sulphur bacteria

within these cells would not be necessary for this to have taken place.

BIOLOGICAL SCIENCES

Satellite DNAs in Crustacea: Two Different Components with the Same Density in Neutral CsCl Gradients

SINCE the first reports of satellite DNAs in the Jonah crab, *Cancer borealis*¹, and in the mouse², satellite DNAs have been described for a number of animal species, both vertebrate and invertebrate. We now report our findings on the satellite DNAs of five species of Crustacea. We find at least one and in some instances two DNA satellites in each species and were surprised to discover that two distinctly different satellite DNAs band at the same density, 1.677 g/cm³, in CsCl. DNAs banding at this density are usually assumed to be "crab poly d(A-T)", the satellite DNA composed of more than 90 per cent alternating adenylate and thymidylate residues^{3,4}. It now seems that this cannot be assumed without further characterization of the DNA species having that density. We emphasize that the satellites described in this note are not mitochondrial in origin: even though we find a mitochondrial DNA of $\rho = 1.688$ g/cm³ in each of the five species, the quantity is too small to be detectable in a "total" DNA

preparation. These data will be presented elsewhere.

The animals used were the Bermuda land crab, *Gecarcinus lateralis*; the edible blue crab, *Callinectes sapidus*; the spider crab, *Libinia dubia*; the Jonah crab, *Cancer borealis*; and the lobster, *Homarus americanus*. DNA was isolated by the method of Marmur⁵ with modifications described previously⁴. We used chiefly gonads or haemocytes. The purified DNAs were analysed by their buoyant density in CsCl as determined with a model E analytical ultracentrifuge or by their melting behaviour registered by a Gilford recording spectrophotometer. Although the total amounts of isolatable DNA varied from one tissue to another, as may be expected, the relative quantities of satellite DNAs compared with main band DNA were fairly constant and characteristic of the animal species.

Fig. 1. Microdensitometer tracings of CsCl isopycnic density gradients of DNA before and after treatment with phenol. Samples were centrifuged in the model E analytical ultracentrifuge at 44,770 r.p.m. for 20 h at 25° C. *a*, Minus phenol treatment: DNA was purified as described from the species of animal indicated. *b*, Plus phenol treatment: samples of the purified DNAs depicted in *a* were brought to 0.1 M NaCl, 0.05 M EDTA (pH 8) in the cold. SDS and 5 M NaCl were added to 2 per cent and 1 M, respectively. After the addition of an equal volume of redistilled phenol (71–74° C fraction), samples were shaken for 1 h in the cold and centrifuged; the aqueous phases were then removed and dialysed in the cold against SSC/10 to remove phenol. *M. luteus* DNA was used as a marker, $\rho = 1.727$ g/cm³.

Buoyant density patterns for the five species are shown in Fig. 1*a*; the data are also summarized in Table 1, which includes the calculation of the percentage of each satellite present. The buoyant density determinations for each species were calculated with reference to either a light or heavy marker. For a light marker, we used "crab poly d(A–T)", $\rho = 1.677$ g/cm³, isolated from the DNA of *Gecarcinus* by two sequential centrifugations in preparative CsCl isopycnic gradients^{4,6}. For a heavy marker we used *M. luteus* DNA, $\rho = 1.727$ g/cm³. The main DNA band had a density of 1.698–1.701 g/cm³ in each species. The DNA from each species was also centrifuged without markers so that satellites could be detected and their concentration relative to the main band DNA calculated (see Fig. 1*a*).

Satellites rich in G+C are found in *Gecarcinus* as reported previously⁴, in *Libinia*, and possibly in *Callinectes*; one is especially prominent in *Homarus*. The buoyant densities of these dense satellites differ from one

species to another (Table 1). A method for their preparative isolation has been described by D. E. G.⁷.

A light satellite ($\rho = 1.677$ g/cm³) is apparent not only in *Gecarcinus* and *Cancer* sp.^{1,4,8}, but also in *Libinia* and *Callinectes*. Whereas others^{9,10} have shown and we have confirmed that glycogen also bands in this CsCl gradient region (indeed, such glycogen bands may contain as much as 98 per cent of the label from ¹⁴C-thymine incorporated into tissues¹¹), the light satellites from all four of the crabs are sensitive to deoxyribonuclease and resistant to amylase, and their absorbances increase on heating. Although these satellites have the density characteristic of the "crab poly d(A–T)" and three of the four have other characteristics typical of this material, the light satellite of *Callinectes* seems to be a special case. This first became evident when purified DNA preparations were exposed to phenol^{12–14}, which extracts "crab poly d(A–T)"¹⁵ and synthetic poly d(A–T)¹⁶. The light satellites from all species except *Callinectes* are lost on treatment with phenol (Fig. 1*b*).

Table 1. CRUSTACEAN DNAs: THEIR BUOYANT DENSITIES IN CsCl AND PERCENTAGE OF TOTAL DNA

	Buoyant density (g/cm ³), with per cent total DNA in parentheses		
	Light	Main band	Heavy
<i>Gecarcinus lateralis</i>	1.677 (18)	1.701 (79)	1.721 (3)
<i>Libinia dubia</i>	1.675 (6)	1.698 (92)	1.714 (2)
<i>Callinectes sapidus</i>	1.676 (15)	1.698 (85)	
<i>Cancer borealis</i>	1.676 (23)	1.698 (77)	
<i>Homarus americanus</i>		1.700 (90)	1.713 (10)

Densities in neutral CsCl were calculated from microdensitometer tracings of analytical ultracentrifugations in a model E centrifuge. "Crab poly d(A–T)" or *M. luteus* DNA was used as a marker. Except for *Libinia* each calculation is the average of two or more model E analyses of two or more DNA preparations. Percentages were determined from areas of Joyce-Loebl microdensitometer scans with a planimeter or by tracing the peaks and weighing cut out areas.

Although "crab poly d(A–T)" bands at a density of 1.677 g/cm³ in CsCl, it has long been known that the linear relationship between G+C content and buoyant density does not hold for that satellite¹⁷. Such a buoyant density is actually consistent with DNA having a G+C content as high as 27 per cent¹⁸. We have obtained further information on G+C content by determining the thermal dissociation properties of the various DNAs. The results with *Libinia*, *Gecarcinus* and *Cancer* DNAs were as expected from previous data on the dissociation of "crab poly d(A–T)" at elevated temperatures⁴; the light satellite DNA in each case melted at 52° C in 0.015 M NaCl–0.0015 M sodium citrate (SSC/10). The results obtained with *Callinectes* and *Gecarcinus* are plotted in Fig. 2*a*. It is clear that the melting behaviour of the *Callinectes* satellite differs from that of the *Gecarcinus* satellite, for an 11° C difference in T_m can be seen in a single sample when the two DNAs are heated together (Fig. 2*a*). The small shoulder at 63° C on the melting curve of *Callinectes* DNA (Fig. 2*a*, inset) was shown by independent experiments to correspond to the d(A+T)-rich satellite (Fig. 2*b*).
